Abstract: About 24 healthy female Sprague-Dawley rats weighing between 300-350 g were used in this study over a 20 day period. They were allocated randomly into 4 groups of 6 animals each. After the creation of 2x2 cm open wound, group 1 was control treated with Gentamycin ointment. Groups 2-4 were treated with Therapeutic ultrasound massage, collagen-calcium alginate film and collagen-calcium alginate film with therapeutic ultrasound. On application, the collagen-calcium alginate film with therapeutic ultrasound was well accepted by the animals without any adverse reaction. Mean percentage of wound contraction were significantly better in group 4 (p<0.05). Faster epithelialization was also seen in the collagen-calcium alginate film with therapeutic ultrasound treated group as compared to the other groups. Collagen is a biocompatible protein that does not interfere with the body’s normal immunologic response and can be used in non-healing chronic wounds which require a trigger to stimulate the normal healing process. In extensive wounds when there is lack of autologous tissue, biomaterials like collagen-calcium alginate may be beneficial and can be used.

Key words: Ultrasound, collagen, calcium alginate, wound, biomaterials, tissues

INTRODUCTION

Wound healing is one of the most complex biological events after birth (Gillitzer and Goebeler, 2001). It is a complex process of the replacement of dead tissue by a vital tissue (Rubin and Farber, 1994). The response of the body to local injury begins very early in the process of inflammation and results in repair and regeneration. Regeneration is a replacement of injured tissue by parenchymal cells of the same type, sometimes leaving no residual trace of the previous injury (Kumar et al., 2003). Repair is a replacement by connective tissue which in its permanent state constitutes a scar (Menetrey et al., 2000). The objectives of any wound management are relief of pain and distress to the animal, functional and cosmetic repair, economic and time efficient procedures and prompt decision making in the event of signs of delayed healing (Cockbill, 2002). In chronic wounds, the major focus of wound healing has been on the relationship between tissue destruction by excessive inflammation and tissue synthesis stimulated by a pro-healing environment. Natural polymers have been increasingly studied for applications in health care due to their biocompatibility, biodegradability and nontoxity (Mali et al., 2006). Collagen-based film is a potentially useful biomaterial, since it is the major constituent of the connective tissue and permits controlled drug release within the target tissues (Gopinath et al., 2004). Alginites are highly absorbent, gel-forming materials with haemostatic properties (Blaine, 1947) and it has long been known that more rapid wound healing occurs when a gel is formed at the wound surface and dehydration is prevented (Winter, 1995). In contact with body fluids, alginites are known to break down to simple monosaccharide-type residues and be totally absorbed. The wound exudate converts the calcium to the sodium salt facilitating the removal of the dressing by dissolution. Any residual fibres remaining within the wound are biodegradable, thus eliminating the need for complete removal (Burrow et al., 1983). Non-invasive treatment with ultrasound therapy hastens wound healing by stimulating cellular activity and protein synthesis (Young and Dyson, 1990). Ultrasound therapy can be useful in accelerating the inflammatory and early proliferative stages of repair. The present study
discusses the effect of collagen-calcium alginate film along with therapeutic ultrasound for management of an extensive wound in a rat.

**MATERIALS AND METHODS**

**Study design:** A complete randomized design was used to determine the efficacy of collagen-calcium alginate film with therapeutic ultrasound for management on wound healing in rats. The experimental protocol was approved by the Animal Care and Use Committee (ACUC) at the Faculty of Veterinary Medicine, Universiti Putra Malaysia (UPM) (Reference No.: 12R158/May 12-April 13).

**Animals:** In this study, a total of 24 female Sprague-Dawley rats (weight 300-350 g) were used and they were randomly divided into 4 experimental groups of 6 rats each.

**Group 1 (n = 6) control group:** Gentamycin ointment (Dutch farm Veterinary pharmaceuticals, Netherlands) was applied after creation of 2x2 cm open wound.

**Group 2 (n = 6):** Therapeutic ultrasound massage treated group. The 2x2 cm open wound was treated using therapeutic ultrasound massage on the periwound skin after smearing the area with coupling gel 10 mts @ 0.5 watts cm$^{-2}$ area (UltraCure PRO™ US-10000, EZUltrasound, Mobridge, South Dakota).

**Group 3 (n = 6):** Collagen-calcium alginate film treated group. The 2x2 cm open wound was treated using collagen-calcium alginate film soaked for 1-2 min in gentamycin (Dutch farm Veterinary pharmaceuticals, Netherlands).

**Group 4 (n = 6):** Collagen-calcium alginate film with therapeutic ultrasound treated group. The 2x2 cm open wound was treated using collagen-calcium alginate film soaked for 1-2 min in gentamycin (Dutch farm Veterinary pharmaceuticals, Netherlands) and therapeutic ultrasound massage was given on the periwound skin after smearing the area with coupling gel 10 mts @ 0.5 watts cm$^{-2}$ area (UltraCure PRO™ US-10000, EZUltrasound, Mobridge, South Dakota). The sample size was designed to minimize the number of animals required which was still adequate to generate statistical analysis. The animals were acclimatized to the laboratory conditions for 1 week prior to the onset of experiment. The rats were individually caged and given commercial pellet and water ad libitum throughout the study.

**Skin preparation:** Rats were anaesthetized with an Intramuscular (IM) injection of ketamine (35 mg kg$^{-1}$) and xylazine (5 mg kg$^{-1}$) into the caudal thigh muscle. When fully anaesthetized, the animals were positioned on their dorsal area which was prepared aseptically for the creation of an open wound (2x2 cm). The skin was disinfected with hibiscrub, containing 0.6% chlorohexidin then with 70% alcohol solution and with 2% iodine solution (Druecke et al., 2004).

Using a sterile millimetre ruler and cotton tipped applicator dipped in sterile methylene blue, a 2 cm$^2$ was drawn on the skin. A full thickness skin defect in which all tissue down to and including the panniculus muscle was excised using no. 15 scalpel blade.

Therapeutic ultrasound massage was given on the periwound skin after smearing the area with coupling gel 10 mts @ 0.5 watts cm$^{-2}$ area (Alliomare et al., 2009).

Collagen-calcium alginate film to cover the wound was soaked in normal saline, kept on the wound and protected with a bandage. The limb was immobilized using a PVC splint and bandage. The same procedure was repeated once a week and the progress in healing was evaluated through wound colour coding, nature and quantity of exudates and odour (James and Bayat, 2003).

**Assessment of the wound:** The progress of open wound healing was recorded at 0, 4, 8, 12, 16 and 20 days post-wounding. All the wounds were digitally photographed in the presence of a standard reference ruler.

A more accurate method for determining the wound area in healing studies is tracing of the wound margins onto a clear plastic sandwich film. In this method, a double layer sterile plastic sandwich bag was placed on the wound for tracing, the layer that comes into contact with the wound can be removed and disposed of accordingly. The outer layer was placed on to a graph sheet and the squares were measured by square counting procedure. The number of squares (0.04 cm$^2$) that lay completely (Nc) and partially (Np) inside the tracing were counted and the area was determined using the following formula:

$$A_{c+p} = (N_c + 0.40 \cdot N_p) \cdot 0.04 \text{ (Richard et al., 2000).}$$

The wound margin at the border between normal skin and the outlined area was considered to be the total wound area. Next the leading edge of advancing epithelium was traced. The area between these two margins was considered to be the area for epithelialization. The area within the margin of advancing epithelium was taken as the area of open or unhealed wound (Bohling et al., 2004). Percentage of wound contraction was calculated by:

**Step 1:** Total wound on day$_y$ = Total wound area day$_y$/original wound area day$_0 \times 100$. 

Step 2: Wound on day \( n \) (\%) = 100 - total wound on day \( n \) as % of original

Histopathological analysis: Rats were euthanized at day 20 post-operation by halothane inhalation and the skin samples were taken for histopathological examination. The skin samples were fixed in 10% formalin solution and embedded in paraffin. Tissue sections of 4.5 mm thickness were cut, stained with Haematoxylin and Eosin (H&E) and examined under light microscope. Digital photomicrographs were captured at representative locations using a digital camera attached to a Nikon Eclipse FX-35DX microscope.

Statistical analysis: Data are expressed as mean±Standard Deviation (SD). The statistical analysis of data was performed using 2-way ANOVA using the SPSS® Statistical package (SPSS, Version 20.0, Chicago, Illinois, USA). The effects with \( p<0.05 \) were considered statistically significant.

RESULTS

The percentage of wound contraction was better in group 3 up to day 12 (59.24%), however it was best in group 4 on days 16 and 20. The difference between groups 2, 3 and 4 compared to group 1 was evident on day 8. The percentage of wound contraction improved from 75.64% (day 16) to almost 93.13% on day 20 in group 4 but group 3 showed an improvement from 17.69% (day 4) to almost 84.55% on day 20 and group 2 showed an improvement from 15.68% (day 4) to almost 78.57% on day 20. Nevertheless, group 4 demonstrated better than average total wound healing throughout the trial (Table 1).

On application, the collagen-calcium alginate films, adhered uniformly to the wound site and were absorbed on the wound site. No unabsorbed remnants were noticed during the next application. In groups 1 and 2 animals, the wound colour was red up to day 12 post-operation and pink in colour from day 16 and 20. Groups 3 and 4 showed bright beefy red colour up to day 12 and it were red from day 16-20. Malodour was observed up to day 12 post-operation in group 1 and 2 animals. In group 3 and 4 mild malodour were observed up to day 8. Serous exudate was noticed up to day 12 in group 1. Mild serous exudate was noticed up to day 8 post-operation in groups 2 and 3 animals. No exudate was seen in group 4 animals throughout the study (Fig. 1 and 2).

Histopathological study: After 20 days of injury, epidermal regeneration was observed in all experimental wounds. Histopathologic comparisons showed that on day 20, collagen-calcium alginate film+ultrasonic massage treated wounds resulted in better re-epithelialization as compared to the control, ultrasonic massage and collagen-calcium alginate film treated rats. In addition, the inflammatory cells were absent in all treated wounds. In the untreated control wounds, though new epithelium was noted to regenerate, inflammatory cells particularly neutrophils and macrophages were still present on the upper dermis. Less scab formation was seen in the wounds treated with collagen-calcium alginate film+ultrasonic massage as compared to the ultrasonic massage, collagen-calcium alginate and untreated control wounds (Fig. 3).

ACKNOWLEDGEMENT

Mal-odour was observed up to day 12 in groups 1 and 2, however in groups 3 and 4 mild mal-odour was observed up to day 8 which may be due to infection (James and Bayat, 2003). The presence of bacterial infection was the common cause for the mal-odour observed because all the wounds were infected. Serous discharge was noticed up to day 12 in group 1 and mild serous discharge was noticed up to day 8 in groups 2 and 3, subsequently, the discharge was reduced because healthy vascular granulation tissue is resistant to infection (Hosgood, 2003; Pope, 1993).

The percentage of wound contraction on post wound days 4 and 8 of all groups showed no significant difference, this may be because of an inherent property of fibroblasts that appears early in the process of wound contraction which after some time, do not contract as forcefully as those that appear later (Bohling et al., 2004). Schaffer et al. (2004) reported that there is increased fibroblast activity of the body until post-wound day 14. On days 12, 16 and 20, group 4 was significantly better than groups 1-3, since basic fibroblast growth factor effectively accelerated wound fibroblast proliferation (Kawai et al., 2000) and has a characteristic myofibroblastic appearance which plays a critical role in closure and healing (Cheng et al., 2002).

CONCLUSION

Collagen-calcium alginate film along with therapeutic ultrasound can be a better wound healing biomaterial in rats. It can be used as a less expensive skin substitute in order to stimulate and promote wound healing in animals.

DISCUSSION

In groups 3 and 4, the application of collagen-calcium alginate film was well tolerated by the animals. The film is easy to apply on the wound without any adverse reaction and was well accepted by all the animals. Calcium alginate contains no cellular materials so they do not elicit any immune response (Andersen et al., 2012). The application of collagen-calcium alginate film treated with therapeutic ultrasound did not show any adhesion of the gauze during wound dressing.

The colour of the wound bed in groups 1 and 2 was red while groups 3 and 4 showed a bright beefy red colour which indicates healthy granulation tissue with neovascularisation (James and Bayat, 2003) and resistance to infection until the epithelial barrier is re-established (Hosgood, 2003; Pope, 1993). The bright red colour observed is due to the micro vascular network throughout the granulation tissue (Tommesen et al., 2000). The basic fibroblast growth factor set the stage for angiogenesis during the first 3 days of wound repair (Schaffer et al., 2004) and plays an important role in granulation tissue formation and the wound healing process (Takehara, 2000). Granulation in all the cases was flat without any exuberant nature, granulation tissue with a smooth surface facilitates migration of epithelial cells (Pope, 1993). On days 16 and 20, the granulation tissue was observed to be pink in colour in groups 1 and 2 which indicates the final stage of wound healing. In groups 3 and 4 the granulation tissue was red in colour due to neovascularisation (James and Bayat, 2003).

The colour of the wound bed in groups 1 and 2 was red while groups 3 and 4 showed a bright beefy red colour which indicates healthy granulation tissue with neovascularisation (James and Bayat, 2003) and resistance to infection until the epithelial barrier is re-established (Hosgood, 2003; Pope, 1993).
