Adult homelessness is a significant public health problem, with nearly 634,000 individuals (both children and adults) experiencing homelessness in the United States on a single night in January 2012. Individuals reporting veteran status are overrepresented among the adult homeless population: approximately 13% (62,619) of adults experiencing homelessness identified as veterans during the January 2012 homeless point-in-time count, despite representing only an estimated 7.1% of the US population. Other work has estimated that veterans’ risk of homelessness is twice that of nonveterans, underscoring possible differences in the experience of homelessness between veterans and nonveterans. Preventing and ending homelessness among veterans—as well as among Americans generally—is a national priority.

Although recent efforts by the US Departments of Housing and Urban Development and Veterans Affairs (VA) appear to be reducing the overall size of the homeless population, additional work is needed to understand the factors that contribute to episodes of homelessness. Adult homelessness often occurs in the context of other negative life events and problems. A variety of individual-level factors appear to contribute to, or are correlated with, homelessness, including disability, mental illness, substance abuse disorders, lack of social or human capital, a history of institutional involvement, and exogenous health and income shocks. Adverse childhood experiences—including abuse, household dysfunction, and neglect—have been shown to predict a multitude of negative outcomes in adulthood, including mental illness, addiction, and chronic disease, frequently in the context of population-representative samples. Meanwhile, the literature linking childhood adversity with adult homelessness has most frequently focused on individuals experiencing homelessness rather than the general population. Various types of specific childhood adversities have been associated with adult homelessness, such as parental substance abuse and childhood abuse and neglect. In addition, a number of studies have identified high rates of adverse childhood experiences among the homeless population.

The interest in understanding the shared and distinct contributors to homelessness and related problems among veterans compared with nonveterans is considerable, given the elevated rates of homelessness after military service. Debates surround how active service might contribute to, or detract from, an individual’s likelihood of poor subsequent outcomes. For example, active service might involve additional stressors related to being removed from support networks (e.g., family and friends) in addition to possible combat exposure. Meanwhile, veteran status also makes available a range of services through the VA that are not provided to nonveterans, and military service may act as a turning point that benefits many individuals, especially those from at-risk backgrounds. Although previous research has sought to identify specific risk factors for and pathways to homelessness among veterans, sources of risk do not appear to differ significantly for veterans and nonveterans, with the exception of military service during the post-Vietnam era. Several studies looking specifically at the role that childhood adversity—or experiences before an individual entered or left active military service—plays in adult homelessness have included a veteran sample or veteran status as a variable in their models. A number of these studies assessed the role of specific adversities, such as family instability, but did not describe the impact of this experience on
adult homelessness. A qualitative study linked childhood abuse and neglect\textsuperscript{54} to individuals’ decisions to join the military in an effort to escape their family of origin, further linking child abuse and neglect to adult homelessness among this veteran sample.

Past work testing links between adverse childhood experiences and adult homelessness is largely based on cross-sectional retrospective studies using exclusively homeless samples or samples of individuals who all reported some sort of childhood adversity. These approaches are limited in their ability to consider alternative pathways, such as individuals who experience high levels of childhood adversity but not homelessness or those who report low levels of adversity in childhood but go on to experience homelessness nonetheless. The complexity of the relationship between adverse childhood experiences and adult homelessness, along with the limitations of the methods used in the existing literature exploring this relationship, underscores the value of a population-based design that uses probability sampling. This design has only been used in 3 of 29 studies published between 1990 and 2012 that explored the relationship between adverse childhood experiences and adult outcomes related to homelessness, mental health, and physical health.

In this study, we considered how experiences and adult outcomes (e.g., among those who are homeless) and characteristics (those with and without a history of active military service).

Additional work is needed to determine the role that childhood adversity may play in poor adult outcomes for individuals with a history of active military service, as well as whether military service moderates the relationship between adverse childhood experiences and adult homelessness. Two divergent hypotheses exist: military service may mitigate risk by providing alternative socialization and discipline for otherwise at-risk youths or exacerbate risk by increasing exposure to trauma. In this study, we considered how experiences of childhood adversity contribute to adult homelessness and related health and mental health problems. We tested the relationship between adverse childhood experiences and outcomes measured in adulthood for the general population of adults in Washington State, then explored possible differences in the adversity-outcome relationship on the basis of individuals’ participation in active military service. By using data collected through the Washington State Behavioral Risk Factor Surveillance System (BRFSS), we addressed a significant limitation in the existing literature: BRFSS data are collected from a probability-based sample representative of the general population, as well as from subsamples of individuals with a history of active military service.

In this study, we aimed to answer 2 questions: Does an individual’s report of adverse childhood experiences predict adult outcomes related to homelessness, mental health, and physical health? Does an individual’s participation in active military service influence the relationship between adverse childhood experiences and adult outcomes related to homelessness, mental health, and physical health?

METHODS

We used data from respondents to the 2010 BRFSS in Washington State. The BRFSS is a state-based health survey coordinated by the Centers for Disease Control and Prevention and cosponsored by the Washington State Department of Health. The BRFSS uses a sample of both landline and cellular telephone numbers to elicit self-reported health behaviors and preventive health practices from adults. The Washington State Department of Health added questions regarding the primary outcome assessed for this study—adult homelessness—to the BRFSS survey instrument during the final 5 months of data collection; therefore, we considered only data from the 6017 respondents to Form A of the 2010 BRFSS. The study team applied weights based on several survey design factors including number of residential telephones in the household, number of adults in the household, geographic stratification, telephone density stratification, and the adult population in each county. Weighting the data minimized potential bias and maximized the generalizability of study findings to the population of Washington State.

Measures

We used several types of data collected by the BRFSS: demographic factors, scales measuring adverse childhood experiences and psychological distress, history of active military service, and measures of adult homelessness and current physical health. In the following paragraphs, we describe the variables included in this study.

Demographic factors. Analyses controlled for participants’ gender and age as well as their self-reported racial and ethnic identification.

Adverse childhood experiences. In this study, we measured childhood adversity by the participants’ responses to 11 questions in the Adverse Childhood Experiences (ACE) Module,\textsuperscript{31} yielding a computed score (possible range = 0–8). This module asks respondents to recall adverse childhood experiences that occurred before age 18 years: physical, sexual, or emotional abuse; witnessing violence against a household member; having a household member who was mentally ill, depressed, or suicidal; incarceration of a family member; parental separation or divorce; and having a parent or caregiver who was addicted to drugs. This scale has been used widely in past work, linking childhood adversity to a range of health and mental health outcomes.\textsuperscript{31,60} Although the scale can be used to rank the severity of childhood adversity—a score of 0 to 2 on the ACE is considered low; 3 to 5, moderate; and 6 to 8, high—we retained the variable as a continuous measure of childhood adversity.

History of active military service. Respondents reported whether they had ever served on active duty in the US Armed Forces. In the analyses presented here, we considered a history of military service to include service in the US Armed Forces, in the regular military, National Guard, or military reserves. History of military service does not include those whose service was limited to training for the reserves or National Guard.

Adult homelessness. We identified respondents as ever experiencing homelessness during adulthood if they indicated that they either (1) lived in a transitional housing program, a hotel or motel paid for by voucher, a domestic violence shelter, or an emergency shelter or (2) in a car or other vehicle, abandoned building, or anywhere outside since age 18 years.
Mental health problem. The Kessler Psychological Distress Scale—intended to identify individuals who do and do not have serious mental illness—includes 6 questions about the individual's experience of symptoms of depression and anxiety during the past 30 days. This 6-item scale has been validated in past work\(^6\)-\(^8\) and is commonly used in epidemiological surveys such as the BRFSS. We used a threshold (total score of \( \geq 13 \)) to indicate individuals with poor mental health. We included mental health problems as an outcome in this study to confirm whether the relationships found here are consistent with prior research.

Health problem. We determined individuals to have a health problem if they reported that in general their health was "fair" or "poor." The response categories for the question were arranged on a 5-point scale ranging from "excellent" to "poor." We included health problems as an outcome in this study to confirm whether the relationships found here are consistent with prior research.

Statistical Analyses

Analyses involved 2 sets of logistic regressions that addressed the research questions guiding the study. First, we used separate logistic regressions to test the relationship between ACE scores and each of the 3 outcomes considering all adults, covarying age, gender, and race/ethnicity. To test for differences in these relationships for adults with active military service, we added an interaction term (active military service \( \times \) ACE score) to each model. We then decomposed significant interaction terms to determine the nature of the effect.

RESULTS

Population demographic characteristics and rates of key variables are provided in Table 1. As would be expected in a survey of the general population, a relatively small proportion of individuals experienced adult homelessness (5.5\%) or current mental health problems (2.9\%); nearly 14\% reported fair or poor health. The average age was 46.2 years (SD = 17.6), and the mean ACE score was 1.7 (SD = 1.9). Roughly one half of the total population was female, and almost 80\% identified as non-Hispanic White.

Of the total sample, approximately 13\% reported a history of active military service. Individuals with a history of active military service were approximately 12.5 years older, significantly more likely to be male, and slightly more likely to identify as non-Hispanic White than those without a history of active military service. These individuals also reported slightly elevated ACE scores (1.8 vs 1.7) and higher rates of adult homelessness (6.0\% vs 5.5\%), mental health problems (3.8\% vs 2.8\%), and health problems (17.5\% vs 13.1\%) than did individuals who did not report a history of military service.

General Population

We used separate analyses to test the hypothesized relationship between childhood adversity and 3 outcomes in the general population: adult homelessness, mental health problems, and health problems. When age, gender, and race/ethnicity were covaried, ACE scores separately predicted increased odds of experiencing homelessness as an adult (\( \text{Exp}(B) = 1.62; \ P < .001 \)), increased odds of reporting a mental health problem (\( \text{Exp}(B) = 1.67; \ P < .001 \)), and increased odds of reporting a health problem, (\( \text{Exp}(B) = 1.36; \ P < .001 \)). Model coefficients are provided in Table 2. The same general pattern of results emerged in analyses considering unweighted data (Table A, available as a supplement to the online version of this article at http://www.ajph.org).

Individuals with a History of Active Military Service

We used a second set of models to test for a moderation effect of a history of active military service on the relationship between ACE score and each outcome. Each of the interaction terms was significant: predicting adult homelessness, \( \text{Exp}(B) = 0.81 (P < .001) \); mental health problems, \( \text{Exp}(B) = 1.33 (P < .001) \); and fair or poor health, \( \text{Exp}(B) = 0.95 (P < .001) \).

Follow-up analyses revealed that higher ACE scores increased the likelihood of homelessness to a greater degree among those without a history of active military service.

*P < .05. **P < .001. cCoefficient suppressed due to < 5 unweighted cases with mental health problems.

Although the risk of mental health problems in adulthood appears to be elevated for individuals with a history of active military service, their risk of adult homelessness and physical health problems is attenuated relative to those without a history of active military service. Although respondents who reported a history of active military service reported only slightly higher ACE scores than those without a history of military service, they did report a greater prevalence of adult homelessness, mental health problems, and physical problems. Nevertheless, the findings indicate that
active military service did partially protect against the negative impact of childhood adversity on adult homelessness and physical health. This protection may, at least in part, involve the greater access to comprehensive health and social welfare services that are available to eligible veterans.

By contrast, a history of active military service exacerbated the risk for mental health problems in adulthood. Other work has suggested that childhood and predeployment factors place servicemen and servicewomen at risk for later poor mental health, especially among veterans who experienced childhood maltreatment (e.g., physical abuse) and combat exposure. The ACE scores used in this study largely indexed childhood maltreatment; however, the BRFSS does not elicit detailed information about the nature of military service or combat exposure. An explanation may be that active military service increases the likelihood of experiencing other situations (e.g., combat exposure) that uniquely challenge mental health without adequately addressing these risks by providing protective or compensating services. Such experiences would especially encourage mental health problems among individuals with higher ACE scores, given associations between childhood adversity and an individual’s ability to adapt to later challenges.

The findings from this study have implications across the life span, calling for additional support for children experiencing adversity as well as a recognition of the role that childhood adversity plays in adult functioning. Supporting children and families to reduce their exposure to adversity, and promoting natural protective factors in children’s lives that can reduce the deleterious effects of adversity, will likely have positive implications for adult homelessness, health, and mental health.

In addition, service providers, researchers, and stakeholders should recognize the links between childhood adversity and adult functioning. This recognition could translate into more effective approaches to service delivery, such as incorporating measures of childhood adversity in screening instruments to assess homelessness risk or identifying particular areas of support that individuals may need to prevent episodes of homelessness.

Although this study provides evidence for the relationship between childhood adversity and adult homelessness and related outcomes—-as well as an indication that one’s history of active military service can convey both protection and risk in terms of adult outcomes—the data and study design have some inherent limitations. Although the construct of history of active military service may imply an individual’s exposure to combat, stressors related to deployment, and access to veterans’ benefits, the data used for this study did not allow us to control for these in our analyses. The dichotomization of the homelessness variable—ever or never homeless—limits the analysis of respondents’ homelessness experiences and does not allow an exploration of the impact of adverse childhood experiences on chronicity of adult homelessness. In addition, on the basis of the study design, the findings from this study are generalizable to the population of the State of Washington; however, these findings may not be generalizable nationally.

This study highlights the need for future research to understand how involvement in military service may moderate outcomes measured in adulthood or during an individual’s postservice period. Specifically, this study indicates that childhood adversity and negative adult outcomes are more prevalent among the population with a history of active military service but that experience in the military may attenuate the risk for some adult outcomes and exacerbate the risk for others. Additional research should focus on veterans’ experiences before, during, and after their involvement in military service. By understanding further the risks experienced before an individual’s entry into military service—as well as the impact of sociodemographic factors such as race and ethnicity—US Armed Forces recruitment strategies could be sensitized to these issues. Moreover, identifying childhood adversity and other risk factors for homelessness among service members leaving the military would support efforts by the US Department of Defense and the VA to prevent homelessness. Additional information related to veterans’ experience of homelessness in adulthood, such as chronicity of homelessness, would further refine the types of interventions intended to address homelessness among former service members and further elucidate the pathways to homelessness among military personnel as well as identify points for screening and intervention, particularly around mental health.
Affairs Serious Mental Illness Treatment Research and Evaluation Center. 2004.
