Crouched gait decreases walking efficiency due to the increased knee and hip flexion during the stance phase of gait. Crouched gait is generally considered to be disadvantageous for children with cerebral palsy; however, a crouched posture may allow biomechanical advantages that lead some children to adopt a crouch gait. To investigate one possible advantage of crouch gait, a musculoskeletal model created in OpenSim was placed in 15 different postures from upright to severe crouch during initial, middle, and final stance of the gait cycle for a total of 45 different postures. A series of optimizations was performed for each posture to maximize transverse plane ground reaction forces in the eight compass directions by modifying muscle forces acting on the model. We compared the force profile areas across all postures. Larger force profile areas were allowed by postures from mild crouch (for initial stance) to crouch (for final stance). The overall ability to generate larger ground reaction force profiles represents a mechanical advantage of a crouched posture. This increase in muscle capacity while in a crouched posture may allow a patient to generate new movements to compensate for impairments associated with cerebral palsy, such as motor control deficits.

1. Introduction

Crouched gait, a common condition among children with cerebral palsy, decreases walking efficiency due to the increased knee and hip flexion during the stance phase of gait [1]. Excessive knee flexion increases the energy requirements of walking [2] which can deteriorate joints and lead to chronic knee pain [3,4]. If left untreated, these symptoms can worsen over time [5]. The lifetime costs for persons born in 2000 with cerebral palsy in the United States are estimated to total $11.5 billion in 2003 US dollars and place great demands on the healthcare system [6].

The disadvantages of crouched gait are well known; however, it remains challenging to elucidate mechanisms that lead to a crouched posture [7]. Several factors have been linked with crouched gait, including muscle weakness, spasticity, tightness [8–10], decreased motor control [11], and skeletal deformities [12]. Despite being studied for decades, a cause and effect relationship between these factors and crouch gait remains unknown, due to the complexity of the musculoskeletal system [10–13–16].

Crouched gait is generally considered to be a negative symptom of cerebral palsy; however, it may afford biomechanical advantages that lead some patients to adopt a crouch gait. Previous study has shown that a crouched posture reduces the capacity of muscles to extend the hip and knee [17], but only in the vertical direction. An athlete gets lower to increase the ability to produce movement in all directions. Similarly, a standing passenger on a moving train gets lower to increase the ability to resist movement. In each case, the movement was produced or resisted by generating ground reaction forces in the transverse plane. A link between crouched gait postures and the capacity of muscles to generate ground reaction forces has several clinical implications. If a crouched posture reduces the capacity of muscles to generate ground reaction forces, patients may have to spend more energy to maintain a crouched posture compared to an upright posture. However, if a crouched posture increases this capacity, patients may be better suited to produce or resist movements to avoid injuries from falling or tripping.

In this study, we used musculoskeletal modeling and optimization to evaluate one such possible advantage of crouch gait. The objective was to determine if posture influences muscles capacity to generate ground reaction forces in the transverse plane during initial, middle, and final stance of a gait cycle. We hypothesized that a crouched posture allows the largest force profile area among postures from upright to severe crouch. Identifying the relationship between posture and ground reaction forces may show an advantage to adopting a crouched posture to compensate for impairments associated with cerebral palsy.

2. Methods

A three-dimensional musculoskeletal model with 15 degrees-of-freedom and 92 muscles-tendon actuators was created in OpenSim [18]. The model consists of a
Different postures from upright to severe crouch during initial stance at 14% of the gait cycle, middle stance at 32% of the gait cycle, and final stance at 50% of the gait cycle. We linearly interpolated nine additional postures between upright and crouched postures from the experimental data during initial, middle, and final stance (Fig. 2). We extrapolated four additional postures (severe crouch) with knee flexion angles greater than crouch. For the initial, middle, and final period of the stance phase, we numbered each posture accordingly: #1 is experimental upright posture, #2 through #10 are interpolated postures, #11 is experimental crouched posture, #12 through #15 are extrapolated postures (severe crouch). The model was placed in a total of 45 postures (15 for each of the three periods) for the study. All of our postures had joint angles that were within 2 standard deviations from the mean joint angles of crouch or upright.

To determine the relationship between posture and ground reaction forces, a series of optimizations was performed for each posture from upright to severe crouch during initial, middle, and final stance. An interior point optimizer (IPOPT) was implemented to maximize the ground reaction forces for the eight compass directions in the transverse plane by modifying muscle forces acting on the model. Each optimization was subject to a set of constraints requiring the center of pressure to be under the stance foot, the vertical ground reaction force to be greater than or equal to zero, and each muscle force was constrained to be less than or equal to its maximum isometric force. A ground reaction force profile was generated for each posture by finding the area of the forces generated in the eight compass directions (Fig. 2). Using the generated force profile area from initial, middle, and final stance, the results were interpolated to show the force profile areas over the entire stance phase of gait. We evaluated our hypothesis by comparing the force profile area between postures.

3. Results

A range of crouched postures allowed the largest ground reaction force profile area during the stance phase of gait (Fig. 3 and Table 1). Over the stance phase, the maximum force profile areas occurred between mild crouch (#5) and severe crouch postures (#12) from initial stance to final stance. During initial stance, interpolated postures (#4–6) between upright and crouch allowed the largest ground reaction force profiles. These postures produced force profile areas within 1% of each other, with posture #5 being the largest (2.582 kN²). Comparatively, experimental upright (#1) and experimental crouched (#11) postures had 12–13% (2.265 and 2.272 kN², respectively) smaller force profile areas, and severe crouch (#15) was roughly 23% smaller (1.999 kN²). The crouched posture (#11) during middle stance produced the largest force profile areas (2.676 kN²) with this trend continuing to final stance. Postures #8–12 produced force profile area within 2% of each other. During final stance, a posture between crouch and severe crouch (#12) allowed the largest ground reaction force profiles (2.514 kN²); however, this force profile area was less than 2% larger compared to crouch (#11). The force profile area (2.487 kN²) of experimental crouch was 7.3% higher compared to

experimental upright and 4% higher than severe crouch during final stance.

4. Discussion

This study examined how posture influences ground reaction forces generated by muscles. We found that the force profile areas for initial stance was highest for postures near mild crouch and decreases as postures move towards upright and crouch. The force profile area increased during middle stance as postures change from mild crouch to crouch and decreases as postures move beyond crouch to severe crouch. The trend for final stance was similar to that of middle stance except that upright showed a slight increase. Our results show that postures between mild crouch and severe crouch postures were able to produce the largest force profile area during the stance phase of gait.

Our study is fundamentally different from Hicks et al. [17], which examined the effect of crouch postures on the capacity of muscles to extend the hip and knee joints. Their study used induced acceleration analysis [13] to determine the joint angular accelerations towards extension resulting from the application of 1 N muscle force to the musculoskeletal model. The joint angular accelerations resulting from the induced acceleration analysis reflects the influence of muscle geometry and posture on the capability of each muscle’s contribution to extend the hip and knee joints. Their study showed almost all of the major hip and knee extensors’ capacities were reduced in crouch gait. This finding suggests a reduction in the ability to generate vertical ground reaction force. In our case, we used optimization to maximize horizontal ground reaction forces in the transverse plane without regard for the vertical ground reaction force. However, a vertical ground reaction force is necessary to achieve the horizontal ground reaction forces (Fig. 2). Our finding suggests an increase in the ability to generate these horizontal forces. Furthermore, our vertical ground reaction forces generated are consistent with the findings in Hicks et al. [17] that crouched posture reduces the ability to generate vertical ground reaction force (Fig. 2).

There were several challenges present in our study and the results should be interpreted in context with our research challenges. First, the optimization procedure implemented to calculate the maximum ground reaction force was static rather than dynamic optimization. Dynamic optimization involves minimizing or maximizing the cost objective function over a period of time; this was not implemented in our study as the model was placed in a given posture while the muscles were able to generate force. Hence, static optimization was better suited for our study. Second, our musculoskeletal model did not incorporate any skeletal abnormalities, such as tibial torsion [22], commonly seen in children with cerebral palsy walking with crouch gait. Our study was focused on examining the different postures and their influence on ground reaction forces. Incorporating bone deformities such as tibial torsion would add additional variables to the investigation, making it difficult to elucidate the effects of ground reaction force relating to the different postures. Hicks et al. [23] showed that deformities such as tibial torsion in patients with cerebral palsy reduces the capacity of the muscles to extend the hip and knee body during the single limb of stance phase. Future studies could include these skeletal deformities in the musculoskeletal model to verify the trends seen from this study across postures during stance phase of gait. Third, several of our postures
were interpolated to find gait data between crouched and normal gait. We also extrapolated some additional postures to look at gait even more severe than crouched. About 80% of our postures, however, were within 1 standard deviation from the mean joint angle of crouched or upright gait. All of our postures’ joint angles were within 2 standard deviations. Finally, the arms in our musculoskeletal model were omitted due to the lack of an upper extremity model with muscles. However, the mass properties of the arms were included in the torso. In a running simulation [24], the arms accounted for less than 1% of both the maximum horizontal and vertical mass center acceleration and therefore its contribution to propulsion and support were minimal.

Despite these challenges, we can draw several conclusions from this study. First, the overall ability to generate larger ground reaction forces and force profile areas represents a mechanical advantage of a crouched posture. This advantage results from an increased capacity of muscles to generate ground reaction forces. This increase in muscle capacity while in a crouched posture may allow a patient to generate new movements to compensate for impairments associated with cerebral palsy, such as motor control deficits. Furthermore, this increase in muscle capacity to generate horizontal ground reaction forces may also rationalize the advantage an athlete gains when adopting a crouch posture in sports. This work can be implemented into future studies to study other bipedal animals, such as birds, to understand why they adopt a crouch gait versus an upright gait as in humans.
