Price Discrimination through Refund Contracts in Airlines*

Diego Escobari† Paan Jindapon‡

August 3, 2012

Abstract

This paper shows how an airline monopoly uses refundable and non-refundable tickets to screen consumers who are uncertain about their travel. Our theoretical model predicts that the difference between these two fares diminishes as individual demand uncertainty is resolved. Using an original data set from U.S. airline markets, we find strong evidence supporting our model. Price-discrimination opportunities through refund contracts decline as the departure date nears and individuals learn about their demand.

1 Introduction

Consider a potential traveler who is planning to buy a plane ticket in advance. However, at this moment, he is not certain whether he will travel. Let his valuation for traveling be $v$. If the airline offers him a refundable ticket now, he will be willing to pay $v$ for that ticket. But if the airline offers him a non-refundable ticket, his willingness to pay should be less than $v$. Once he knows with certainty whether he wants to travel, there is no reason why he should be willing to pay more for a refundable ticket than for a non-refundable ticket.

This paper presents a theory that explains how a monopolist can use refundable and non-refundable tickets to screen consumers and extract more surplus when consumers have to select a contract before knowing their demand with certainty. In the simple two-period model, the airline will offer both ticket types in advance to consumers who are uncertain about their demand and have different willingness to pay. We derive optimal refundable and non-refundable fares that depend on each consumer’s willingness to pay and the probability of travel. Consumers with high willingness to pay buy refundable tickets, and consumers with low willingness to pay buy non-refundable tickets. Furthermore, we find that the difference between these two fares consists of a quality component—the refundability value—and a price-discrimination component. A comparative-statics analysis provides an empirical implication of the model: the gap between the two fares diminishes as the date of departure approaches and consumers become more certain about their individual demand. Therefore, the airline’s ability to separate consumer types and to price discriminate vanishes.

In the empirical section we test the main empirical implication from the theory. We collected from the online travel agency Expedia.com an original panel data set of refundable fares, non-refundable fares, and seat inventories across 96 U.S. domestic monopoly routes at various days prior to the departure date. The data collection focuses on posted one-way economy-class fares to control for price differentials associated with other ticket

1This ex-ante willingness to pay for a non-refundable ticket is analogous to the option price in Cicchetti and Freeman (1971). Schmalensee (1972) and Graham (1981) show that the option price may be greater or smaller than the expected willingness to pay.

2Even though we focus on airlines, the results can also be applied to other industries where goods are sold in advance with a refundable option, such as cruises, car rentals, and lodging.
restrictions; for example, Saturday-night stayover, minimum and maximum stay, first-class travel, and connecting legs. These restrictions are commonly used as ‘fences’ to implement other forms of price discrimination and congestion pricing and to deal with aggregate demand uncertainty. The panel structure of the data controls for unobservable time-invariant carrier-, route-, and flight-specific characteristics. Moreover, the fact that both fares were collected at the same time for the same seat allows us to control for unobserved time-variant seat-specific characteristics. The estimation method, which takes into account the dynamic adjustment between the difference in fares and seat inventories, shows strong evidence that price discrimination through refund contracts vanishes as the departure date nears. In addition, a nonparametric specification indicates that most of the individual demand uncertainty, as implied by the carriers’ pricing strategy, is resolved during the last two weeks prior to the departure date.\(^3\)

In the literature, Gale and Holmes (1993) and Dana (1998) use advanced-purchase discounts as a means of price discrimination to improve capacity utilization in monopolistic and competitive markets respectively. In contrast, we show that an airline monopoly can use a refundability option to screen consumers and increase the airline’s expected profit. Courty and Li (2000) suggest a theoretical model for a monopolist that price discriminates via refund contracts consisting of a price a buyer has to pay in advance and a refund the buyer can receive after he learns his valuation of the good. While Courty and Li’s purpose is to find an optimal refund contract consisting of an advance payment and a refundable amount, our goal is to find an optimal contract consisting of a non-refundable price and a refundable price for each type. In a related work, Akan et al. (2008) present a generalization of Courty and Li (2000) with consumers who learn their valuations gradually and with a seller that can vary the length of time during which the tickets are refundable. Bilotkach (2009) presents a model explaining refund contracts under costly capacity and demand uncertainty.

The rest of the paper is structured as follows. Section 2 presents the theoretical model, including the consumer’s problem and the airline’s problem, and describes the airline’s price menu in equilibrium. Section 3 presents the empirical analysis by first describing the

\(^3\)These results, in addition, help explain the large price dispersion in airlines documented in Borenstein and Rose (1994) and more recently in Gerardi and Shapiro (2009).
data, then setting the empirical model, and closing with the results. Section 4 concludes.

2 Theoretical Analysis

Consider a monopolistic airline that sells homogeneous seats on a flight to consumers whose type, high (H) or low (L), is not observable to the airline. In airline markets, it is common to see consumers buy tickets in advance despite uncertainty in their travel plans. In our two-period model, consumers have unit demands and have to decide whether to buy a ticket in period 1. However, they learn in period 2 whether they want to fly or not (i.e., demand equals 1 or 0). Let travel and no travel be mutually exclusive states of nature in which a consumer wants and does not want to travel respectively. The risk in the state of nature that each consumer faces is an individual risk that is independent from those of other consumers. For \( \theta = H, L \), we let \( \pi_\theta \) denote the probability that type \( \theta \) consumer wants to travel and hence \( 1 - \pi_\theta \) the probability that the consumer does not want to travel. Both types have a positive valuation of traveling \( v_\theta \) and share the same utility function \( u \) with \( u' > 0 \) and \( u'' \leq 0 \). We normalize \( u \) so that \( u(0) = 0 \).

2.1 The Consumer’s Problem

In period 1, the airline offers refundable and non-refundable tickets to all consumers. If a type \( \theta \) consumer buys a refundable ticket at price \( p \) in period 1 and learns that he wants to travel in period 2, then he will use the ticket and his utility will be \( u(v_\theta - p) \). If he learns that he does not want to travel, he will request a refund and his utility will be his status quo, \( u(0) \), which is equal to zero. In contrast, if the consumer buys a non-refundable ticket at price \( p \), his utility will be \( u(v_\theta - p) \) if he wants to travel and \( u(-p) \) otherwise. Under expected utility theory, type \( \theta \) consumer’s expected utility from buying a refundable ticket at price \( p \) is denoted by

\[
U^r_\theta(p) = \pi_\theta u(v_\theta - p)
\]

(1)

and type \( \theta \) consumer’s expected utility from buying a non-refundable ticket at price \( p \) is denoted by

\[
U^{nr}_\theta(p) = \pi_\theta u(v_\theta - p) + (1 - \pi_\theta)u(-p).
\]

(2)
Note that there is no time value of money. If a consumer does not buy a ticket, his utility in period 2 will be zero in both states.\(^4\) Then type \(\theta\)’s reservation price for a refundable ticket is \(v_\theta\) and type \(\theta\)’s reservation price for a non-refundable ticket is \(c_\theta\) such that \(U^\text{nr}_\theta(c_\theta) = 0\); i.e.,

\[
\pi_\theta u(v_\theta - c_\theta) + (1 - \pi_\theta)u(-c_\theta) = 0.\tag{3}
\]

Note that \(c_\theta\) is an increasing continuous function of \(\pi_\theta\) from \([0, 1]\) onto \([0, v_\theta]\).\(^5\)

Now we explain how a consumer decides which type of ticket to buy when the airline simultaneously offers non-refundable and refundable tickets in period 1. Formally, let the airline offer a price menu \((p^\text{nr}, p^r)\) in which \(p^\text{nr}\) represents a non-refundable price and \(p^r\) represents a refundable price. Each consumer’s action set includes buy a refundable ticket, buy a non-refundable ticket, and not buy a ticket. We find that type \(\theta\) consumers best response is given by:

- buy a refundable ticket if \(U^r_\theta(p^r) \geq U^\text{nr}_\theta(p^\text{nr})\) and \(U^r_\theta(p^r) \geq 0\),
- buy a non-refundable ticket if \(U^\text{nr}_\theta(p^\text{nr}) > U^r_\theta(p^r)\) and \(U^\text{nr}_\theta(p^\text{nr}) \geq 0\),
- buy no ticket if \(U^\text{nr}_\theta(p^\text{nr}) < 0\) and \(U^r_\theta(p^r) < 0\).

This means that a consumer observes \(p^\text{nr}\) and \(p^r\) before choosing the ticket type that gives the highest expected utility. If \(p^\text{nr}\) and \(p^r\) are so high that both corresponding expected utilities are negative, i.e., worse than his status quo, he will not buy any ticket. Type \(\theta\) consumers best response can be illustrated in Figure 1. The \((p^\text{nr}, p^r)\) space is divided into three regions by the L-shaped \(\overline{U}_\theta\), which includes all \((p^\text{nr}, p^r)\) such that \(\max\{U^\text{nr}_\theta(p^\text{nr}), U^r_\theta(p^r)\} = 0\), and the dashed curve, which includes all \((p^\text{nr}, p^r)\) such that \(U^\text{nr}_\theta(p^\text{nr}) = U^r_\theta(p^r) > 0\).\(^6\) We find that, in region 1, the consumer buys a non-refundable ticket; in region 2, the consumer buys a refundable ticket; and in region 3, the consumer does not buy a ticket. Note that region 1 includes the vertical part of \(\overline{U}_\theta\) except \((v_\theta, c_\theta)\) and region 2 includes \((v_\theta, c_\theta)\), the horizontal part of \(\overline{U}_\theta\), and the dashed curve.

---

\(^4\)It is possible to extend the model by imposing a cost on the consumer who wants to travel but does not have a ticket so that his utility is lower than zero. However, the differences in the results are immaterial.

\(^5\)For example, if \(u(x) = \ln(1 + x/1000)\), \(v_L = 500\), and \(\pi_L = 0.6\), then we find that \(c_L = 268\).

\(^6\)Using the implicit function theorem, we find that the slope of the dashed curve is positive. If \(u\) is linear, the dashed curve becomes a straight line with slope equal to \(1/\pi_\theta\), as shown in Figure 1.
2.2 The Airline’s Problem

We now turn to the airline’s pricing problem. In particular, we are interested in a separating equilibrium where type $H$ consumers buy refundable tickets and type $L$ consumers buy non-refundable tickets. We solve for the optimal separating price menu and show that it constitutes an equilibrium under reasonable conditions.

Let the numbers of type $H$ and type $L$ consumers in period 1 be $N_H$ and $N_L$ and the numbers of type $H$ and type $L$ consumers that want to travel in period 2 be $n_H = \pi_H N_H$ and $n_L = \pi_L N_L$ respectively. The airline, which has zero marginal cost and a capacity at least $n_H + n_L$, announces $p_{nr}$ and $p_r$ at the beginning of period 1. Since the airline does not know each consumer’s type, we let the airline derive its belief about each consumer type from $N_H$ and $N_L$. After observing the prices, consumers’ strategies could be either pooling (i.e., both types choose the same action) or separating (i.e., each type chooses a different action). We define an equilibrium as a combination of the airline’s beliefs and strategy $(p_{nr}, p_r)$ and each consumer’s strategy given $\theta$ and $(p_{nr}, p_r)$ so that the airline’s expected profit and each consumer’s expected utility are maximized.

We are interested in separating equilibria in which each consumer type buys a different type of ticket. However, we cannot identify which consumer type buys which type of ticket without further assumptions about $v_\theta$ and $\pi_\theta$ for $\theta = H, L$. Thus we assume negative correlation between valuation and certainty about travel (i.e., $v_H > v_L$ and $\pi_H < \pi_L$). This is a realistic assumption because most business travelers have a higher willingness to pay for a ticket and are less certain about their travel than pleasure travelers. As a result, type $H$ consumers buy refundable tickets, type $L$ consumers buy non-refundable tickets, and the airline’s profit is equal to $N_L p_{nr} + n_H p_r$. Given these consumers’ strategies, we solve for the airline’s optimal price menu below and present the solution in Proposition 1. Nonetheless, this separating price menu does not always constitute an equilibrium because it may be possible for the airline to increase profit by using an alternative price menu inducing other responses from the consumers. We provide necessary and sufficient conditions for existence of this separating equilibrium in Proposition 2.
The airline’s optimization problem can be written as:

\[
\max_{p^{nr}, p^r} N_L p^{nr} + n_H p^r \tag{4}
\]

s.t.

\[
U^r_H(p^r) \geq U^{nr}_H(p^{nr}) \tag{5}
\]

\[
U^{nr}_{L}(p^{nr}) \geq U^r_{L}(p^r) \tag{6}
\]

\[
U^r_H(p^r) \geq 0 \tag{7}
\]

\[
U^{nr}_{L}(p^{nr}) \geq 0 \tag{8}
\]

The incentive-compatibility constraints, (5) and (6), are required for type \(H\) consumers to prefer buying a refundable ticket and type \(L\) consumers to prefer buying a non-refundable ticket, while the participation constraints, (7) and (8), are required for both consumer types to buy a ticket. There are two possibilities: either \(c_L \geq c_H\) or \(c_L < c_H\), illustrated in Figure 2. The shaded areas show \((p^{nr}, p^r)\) such that all the constraints are satisfied with (5) and (8) binding. If \(c_L \geq c_H\), type \(L\) consumers are willing to pay more for a non-refundable ticket while type \(H\) consumers are willing to pay more for a refundable ticket. It follows that the airline can separate the consumers by simply setting \((p^{nr}, p^r) = (c_L, v_H)\) which corresponds to the northeast corner of the shaded area in the left panel.\(^7\)

Now consider the case where type \(L\) consumers are willing to pay less for a non-refundable ticket than type \(H\) consumers (i.e., \(c_L < c_H\)). If the airline sets \((p^{nr}, p^r) = (c_L, v_H)\), type \(H\) consumers will find non-refundable tickets more attractive than refundable tickets because \(U^r_H(v_H) < U^{nr}_H(c_L)\). To obtain the separating equilibrium, the airline must lower the refundable price to be no larger than \(m\) so that \(U^r_H(m) = U^{nr}_H(c_L)\). That is,

\[
\pi_H u(v_H - m) = \pi_H u(v_H - c_L) + \left(1 - \pi_H\right) u(-c_L). \tag{9}
\]

\(^7\)For example, let \(u(x) = \ln(1 + x/1000)\). For type \(L\) consumers, \(v_L = 500\) and \(\pi_L = 0.6\), so \(c_L = 268\). For type \(H\) consumers, \(v_H = 800\) and \(\pi_H = 0.3\), so \(c_H = 185\). Since \(c_L \geq c_H\), the airline sets \((p^{nr}, p^r) = (268, 800)\).
We say that the difference between $v_H$ and $m$ is the information rent taken by type $H$ consumers. The airline offers this discount to prevent type $H$ consumers from buying a non-refundable ticket. In this case the solution is $(p^{nr}, p^r) = (c_L, m)$ which corresponds to the upper corner of the shaded area in the right panel.\footnote{Let $u(x) = \ln(1 + x/1000)$. For type $L$ consumers, $v_L = 500$ and $\pi_L = 0.6$, so $c_L = 268$. For type $H$ consumers, $v_H = 800$ and $\pi_H = 0.5$, so $c_H = 323$. We find that $m = 678$. Since $c_L < c_H$, the airline sets $(p^{nr}, p^r) = (268, 678)$.} We summarize these results in Proposition 1.

**Proposition 1** Given the following assumptions:

(i) $v_H > v_L > 0$.

(ii) $0 < \pi_H < \pi_L < 1$.

(iii) $u' > 0$ and $u'' \leq 0$.

The airline’s optimal price menu so that type $L$ consumers buy non-refundable tickets and type $H$ consumers buy refundable tickets is given by

\[
(p^{nr}, p^r) = \begin{cases} 
(c_L, v_H) & \text{if } c_L \geq c_H \\
(c_L, m) & \text{if } c_L < c_H
\end{cases}
\]  

(10)

where $c_0$ and $m$ are defined in (3) and (9) respectively.

**Proof** See the above argument.

Given the separating response in which type $L$ consumers buy non-refundable tickets and type $H$ consumers buy refundable tickets, the airline maximizes its profit by always selling non-refundable tickets at $c_L$. If a type $L$ consumer is willing to pay more for a non-refundable ticket than a type $H$ consumer (i.e., $c_L \geq c_H$) then the type $H$ consumer will find a refundable ticket priced at $v_H$ more attractive than a non-refundable ticket. Despite the fact that a non-refundable ticket costs less, it gives a type $H$ consumer lower expected utility than a refundable ticket. Hence the optimal pricing menu is $(p^{nr}, p^r) = (c_L, v_H)$. In contrast, if a type $H$ consumer is willing to pay more for a non-refundable ticket than a type $L$ consumer (i.e., $c_H > c_L$) he will find a non-refundable ticket priced at $c_L$ more attractive.
than a refundable ticket priced at $v_H$. So the airline has to lower the refundable price to $m$ so that the expected utilities from both ticket types are equal, and by our tie-breaking rule, he will buy a refundable ticket.

Even though the airline sells tickets to the two consumer types at different prices, we cannot claim that the difference between the two prices, $p' - p^{nr}$, is solely due to price discrimination because the two ticket types have different qualities. We decompose the fare difference into two components: $p' - v_L$ and $v_L - p^{nr}$. The second component, which is equal to $v_L - c_L$, is the refundability value to type $L$ consumers because it is the difference in willingness to pay for a refundable ticket versus a non-refundable ticket. If $c_L \geq c_H$, the first component equals the difference in willingness to pay for a refundable ticket between the two consumer types. Since the airline can sell refundable tickets to type $H$ consumers at a higher price than what type $L$ consumers are willing to pay, we say that this component is the airline’s price discrimination. If $c_L < c_H$, the price discrimination component is smaller because the airline has to lower the refundable price to separate consumers.

### 2.3 Equilibrium Prices

We have shown in Proposition 1 that the airline’s optimal price menu to obtain a separating response in which type $H$ consumers buy refundable tickets and type $L$ consumers buy non-refundable tickets is $(p^{nr}, p') = (c_L, v_H)$ if $c_L \geq c_H$ and $(p^{nr}, p') = (c_L, m)$ if $c_L < c_H$. However, this separating response may not be best to the airline and hence the described price menu may not constitute an equilibrium. For instance, if there are only a few type $H$ consumers, a pooling response in which all consumers buy refundable tickets may be more profitable. We provide necessary and sufficient conditions for the airline to find the separating response most profitable in the following proposition.

**Proposition 2** Given the following assumptions:

1. $v_H > v_L > 0$.
2. $0 < \pi_H < \pi_L < 1$.
3. $u' > 0$ and $u'' \leq 0$.  

(iv) The number of type $\theta$ consumers in period 1 is $N_{\theta} > 0$ and the numbers of type $\theta$ consumers that want to travel in period 2 is $\pi_{\theta} N_{\theta}$.

Necessary and sufficient conditions for existence of an equilibrium where type $L$ consumers buy non-refundable tickets and type $H$ consumers buy refundable tickets are

$$\frac{N_H}{N_L} \geq \frac{\pi_{LV_L} - c_L}{\pi_H (v_H - v_L)}$$

(11)

if $c_L \geq c_H$ and

$$\frac{\pi_{LV_L} - c_L}{\pi_H (m - v_L)} \leq \frac{N_H}{N_L} \leq \frac{c_L}{\pi_H (v_H - m)}$$

(12)

if $c_L < c_H$, where $c_\theta$ and $m$ are defined in (3) and (9) respectively.

Proof See Appendix.

To assure that the separating response where the airline sells refundable tickets to type $H$ consumers and non-refundable tickets to type $L$ consumers constitutes an equilibrium, we must show that the airline’s maximum profit given this response is not lower than its maximum profit from each of other consumers’ responses. The inequality in (11) and the left inequality in (12) guarantee that the separating price menu from (10) yields a higher profit than the optimal price menu such that both types buy refundable tickets. Both inequalities suggest that $N_H/N_L$ must be large enough because the airline makes more profit from type $H$ and less profit from type $L$ with the separating price menu. To maximize its profit while making both type $H$ and type $L$ consumers buy refundable tickets, the airline must set $p^{nr}$ really high so that no one would want to buy a non-refundable ticket. With this pooling price, the airline makes less profit from type $H$ consumers because it has to lower $p^r$ to $v_L$ so that refundable tickets attract all consumers. However, the airline makes more profit from type $L$ consumers by selling them refundable instead of non-refundable tickets because of risk aversion. We show in the appendix that $c_L \leq \pi_{LV_L}$ whenever $u'' \leq 0$ and hence the profit from selling non-refundable tickets to type $L$ consumers, $N_L \pi_{LV_L}$, is smaller than $N_L \pi_{LV_L}$ which is the airline’s profit when selling them refundable tickets.

---

9 In the proof of Proposition 2, we compare the airline’s profit from the optimal price menu in (10) to profits from other optimal price menus given other consumers’ responses.

10 Consider the example in Footnote 7. If $N_H = N_L = 50$, the separating price menu yields $(15 \times 800) + (50 \times 268) = 25,400$ in profit which is greater than profit from the pooling-on-refundable price menu,
In addition to pooling-on-refundable response described above, we also consider other consumers’ responses in the proof of Proposition 2 and find that the separating price menu dominates all other responses regardless of $N_H$ and $N_L$ when $c_L \geq c_H$. However, when $c_L < c_H$, another candidate of equilibrium arises because the airline might prefer selling only refundable tickets to type $H$ consumers and no tickets at all to type $L$ consumers. Remember that the optimal separating price menu given $c_L < c_H$ is $(p^{nr}, p^r) = (c_L, m)$. Since the airline sells refundable tickets at a discounted price, $m$, it may be more profitable to the airline, when $N_H$ is large enough, to set $p^{nr}$ very high so that a non-refundable ticket is unattractive to everyone and increase $p^r$ to $v_H$.\footnote{Following with the example in Footnote 8, with $N_H = 90$ and $N_L = 10$. The separating price menu yields $(45 \times 678) + (10 \times 268) = 33,190$ in profit which is smaller than profit from selling only refundable tickets to type $H$, $45 \times 800 = 36,000$.}

In short, the separating price menu in (10) constitute an equilibrium when the proportion of type $H$ to type $L$ population is neither too large nor too small. If there are relatively many type $L$ consumers, the airline will prefer selling refundable tickets to both types at $v_L$. On the other hand, if there are relatively many type $H$ consumers and the willingness to pay for a non-refundable tickets of type $L$ is less than that of type $H$, the airline will prefer selling only refundable tickets to type $H$ at $v_H$ and no tickets at all to type $L$.

The restrictions (11) and (12) can be simplified when consumers are risk neutral because, as we see from (3), $c_L = \pi_L v_L$ when $u'' = 0$, and as a result, the inequality in (11) and the left inequality in (12) are automatically satisfied. So we can say that when consumers are risk neutral and $c_L \geq c_H$, the airline’s separating price menu given in Proposition 1 always constitues an equilibrium. In contrast, if $c_L < c_H$, we still need to impose the right inequality of (12) even when $u'' = 0$. Nonetheless, we can say that it is very likely to see the separating price menu in equilibrium if consumers are slightly risk averse because both restrictions on $N_H/N_L$ are easier to satisfy.

\begin{align*}
(15 \times 500) + (30 \times 500) &= 22,500. \text{ If the } N_H/N_L \text{ ratio was not large enough, say } N_H = 10 \text{ and } N_L = 90, \\
\text{the airline would try to sell refundable tickets to all consumers and make } (3 \times 500) + (54 \times 500) &= 28,500 \text{ in profit instead of } (3 \times 800) + (90 \times 268) = 26,520 \text{ from separating.}
\end{align*}
2.4 Empirical Implication

We now provide an interesting empirical implication from this theoretical model: the gap between refundable and non-refundable prices diminishes as the flight date nears and the consumers become more certain about their travel plans. Let $\pi_H$ and $\pi_L$ be continuous functions of $\tau$, the time length between period 1 and period 2 in the theoretical model (i.e., the number of days between when agents consider buying a ticket and the departure date). We assume the following:

(i) $\pi_L(\tau)$ and $\pi_H(\tau)$ are non-increasing in $\tau$.

(ii) $\pi_L(\tau) \geq \pi_H(\tau)$ for all $\tau$.

(iii) $\pi_L(0) = \pi_H(0) = 1$.

The possibility that each passenger becomes more certain about traveling because he may have more information as the departure date approaches can justify (i). Conditions (ii) and (iii) mean that type $L$ travelers are more certain about traveling than type $H$ travelers on any day prior to departure and that there is no uncertainty about traveling on the departure date. These are practical conditions because most business travelers are more uncertain about their travel than pleasure travelers when they buy tickets in advance, and all agents know with certainty whether they are flying on the departure date.

We learn from (3) that $c_\theta$ is a continuous function of $\pi_\theta$ and that $dc_\theta/d\pi_\theta > 0$. It follows from the above assumptions that when $\tau$ is small (i.e., close to departure date) both $\pi_L$ and $\pi_H$ will be close to 1 and, as a result, $c_L < c_H$. In contrast, when $\tau$ is large, it is possible that the difference between $\pi_L$ and $\pi_H$ is so large that $c_L \geq c_H$. We show below that regardless of whether $c_L \geq c_H$ or $c_L < c_H$ the gap between refundable and non-refundable prices are smaller as $\tau$ decreases.

If $c_L \geq c_H$, the airline sets $(p^{nr}, p^r) = (c_L, v_H)$. Since $\pi_L$ increases as $\tau$ decreases, we find from (3) that $c_L$ also increases and the gap between $p^r$ and $p^{nr}$ becomes smaller. On days close to departure, $\pi_H$ will be large enough that $c_H > c_L$ and the airline sets $(p^{nr}, p^r) = (c_L, m)$. From (9) we find that, as $\pi_H$ approaches 1, $m$ converges to $c_L$. Therefore, the difference between the refundable and non-refundable fares diminishes as the departure date
approaches (i.e., $\tau \to 0$). When $\tau = 0$, the airline sets $(p^{nr}, p^r) = (c_L, c_L) = (v_L, v_L)$.\textsuperscript{12} There is only one price on the departure date because there is no benefit from paying more for a refundable ticket when individual demand uncertainty is fully resolved. The airline’s ability to screen consumers vanishes, making price discrimination opportunities through refund contracts disappear.

### 3 Empirical Analysis

#### 3.1 Data

We collected from the online travel agency Expedia.com the lowest posted refundable and non-refundable one-way economy-class fares for 96 flights that departed on June 22, 2006. Following Stavins (2001) we focused on a single day, Thursday, to control for price differentials associated with systematic peak-load pricing over days of the week. The data form a panel with 96 cross-sectional units observed over 28 periods. Each cross-section corresponds to a specific carrier’s non-stop flight between a city pair. Fares were recorded every three days, from 82 days prior to departure to one day prior to departure. The carriers considered are American, Alaska, Continental, Delta, United, and US Airways. The share of each carriers’ flights in the data set was chosen to be close to the carrier’s share of the U.S. market.

A monopoly route, as defined by Borenstein and Rose (1994), is a route on which a single carrier operates more than 90 percent of the weekly direct flights. Following a similar but stricter criterion, each of our 96 monopoly routes is operated by a carrier who is the sole supplier of non-stop service between the city pair. Tickets with one or more stops and first-class travel tickets are considered to be of significantly different quality. By picking non-stop flights and one-way fares we control for price differences associated with different ticket restrictions, cost differences associated with round-trip tickets, and price variations related to more sophisticated itineraries. Dealing with one-way tickets is particularly important in our model because the traveler may also be uncertain about the

\textsuperscript{12}As the date of travel approaches the model allows for the possibility that we move from the separating equilibrium to other equilibria. This will not be an issue if $N_H$ and $N_L$ satisfy the conditions in Proposition 2 for all $\tau$. 
Figure 3 shows the average refundable and non-refundable fares across all 96 monopoly routes at different points prior to the departure date. The dashed lines are 95% confidence intervals for the means and are calculated separately for every point in time using the t-distribution. The figure shows that there is a strong tendency for non-refundable fares to increase faster than refundable fares, suggesting that as the flight date nears consumers resolve their individual demand uncertainty.

[Insert Figure 3 here.]

3.2 Empirical Model

The panel structure of the data allows us to control for time-invariant flight-, carrier-, and route-specific characteristics. This includes all time-invariant characteristics in Stavins (2001), who used a cross section of tickets. However, there are time-variant cost components that arise at seat-level. Stochastic peak-load pricing, as explained in Borenstein and Rose (1994), depends on the degree of price adjustment as demand is revealed over time. Prices on the same flight can vary with the purchase date and with the probability, at the time the ticket is sold, that demand will exceed capacity. In models of aggregate demand uncertainty where sellers commit to a price schedule, Dana (1998, 1999) considers the existence of an effective cost of capacity, which also changes across seats.

To control for these time-variant seat-specific characteristics, we take advantage of the fact that both refundable and non-refundable fares were obtained at the same time for the same seat. Hence, taking the difference between these two fares will wipe out these characteristics.\(^\text{13}\) The logarithmic specification of the dynamic reduced-form model that we estimate is given by

\[
\ln(p_{ij,t}^r - p_{ij,t}^{nr}) = \alpha \ln(p_{ij,t-1}^r - p_{ij,t-1}^{nr}) + \beta_1 \tau_{ij,t} + \beta_2 \tau_{ij,t}^2
\]

\[
+ \beta_3 \tau_{ij,t}^3 + \beta_4 LD_{ij,t} + \nu_{ij} + \varepsilon_{ij,t},
\]  

\(^{13}\text{Controlling for these costs has limited the availability of empirical papers on airline price discrimination. Stavins (2001) looks at price differentials due to ticket restrictions; however, those ticket restrictions are understood to solve the peak-load pricing problem as well (see Courty and Li, 2000, p. 716).}\)
where the subscript \(i\) refers to flight, \(j\) to route, and \(t\) to time. Following the theoretical section, \(p_r^i\) and \(p_{nr}^i\) are the refundable and non-refundable ticket prices, and \(\tau\) is the number of days prior to departure when the two prices were recorded. Thus, \(\tau^2\) and \(\tau^3\) correspond to days in advance squared and cubed respectively. \(LOAD\) is the load factor, defined as the ratio of occupied seats to total seats. Given that overbookings are usually a small fraction of the total number of tickets, \(LOAD\) is assumed to be proportional to bookings.\(^{14}\) Finally, \(\nu_{ij}\) denotes the unobservable flight-specific effect and \(\varepsilon_{ijt}\) denotes the remaining disturbance.

We include \(LOAD\) in Equation 13 to account for the possibility that if \(\pi_L > \pi_H\), refundable tickets will consume less capacity than non-refundable tickets. The theoretical literature on aggregate demand uncertainty (e.g., Dana (1998, 1999), Gallego and van Ryzin (1994), and Zhao and Zheng (2000)) predicts that prices will increase as available capacity decreases.\(^{15}\) These models do not consider refundable tickets. However, in a generalization of these models, \(LOAD\) would have a larger effect on non-refundable tickets. Hence, we expect \(LOAD\) to be negatively correlated with the price gap, and not including it can bias the estimates toward finding convergence in fares. As the difference between \(\pi_L\) and \(\pi_H\) disappears as both approach one at departure, any effect of \(LOAD\) on the gap should disappear as well.

The lagged dependent variable is included in Equation 13 to allow for dynamics in the underlying process. The GMM estimators allow us to assume only weak exogeneity of \(LOAD\).\(^{16}\) Consistent estimates of the parameters can then be obtained using the difference and system GMM estimators proposed in Holtz-Eakin et al. (1988), Arellano and Bond (1991), Arellano and Bover (1995), and Blundell and Bond (1998). Then consumers can

\(^{14}\)\(LOAD\) was obtained from the seat-availability map, where the available or prime seats reported by Expedia.com are counted as available seats. The estimation procedure controls for any additive measurement error. Using a different data set, Escobari (2009) uses this variable to control for capacity utilization to find evidence of systematic peak-load pricing.

\(^{15}\)Escobari (2009) and Alderighi et al. (2012) find empirical evidence supporting this argument.

\(^{16}\)Bilotkach et al. (2011) present a specification in which the load factor is affected by previous prices, consistent with our assumption of weak exogeneity of \(LOAD\). Moreover, Escobari (2012) estimates a dynamic demand equation that shows evidence that cumulative bookings should not be treated as exogenous. Weak exogeneity is also consistent with Deneckere and Peck (2012), who propose a price posting theory in which consumers behave dynamically.
behave dynamically, and weak exogeneity of \( LOAD \) means that the number of seats sold up to time \( t \) can be affected by past realizations of the differences in fares but must be uncorrelated with future realization of the error term.

To address nonlinearities in a more flexible way, we also estimate a nonparametric model with fixed effects. The estimation follows the kernel methods of Racine and Li (2004) for a mix of discrete (\( \tau \)) and continuous (\( LOAD \)) data types.\(^{17}\) This approach allows for interactions between \( \tau \) and \( LOAD \) and for nonlinearities in and between both. The smoothing parameters are calculated with least squares cross-validation, and we will summarize the results using a partial regression plot. This presents the multivariate regression function via a bivariate plot with \( LOAD \) held constant at its median and permits a direct comparison of the parametric and nonparametric results.

### 3.3 Regression Results

From the summary statistics presented in Table 1, we find that refundable fares are, on average, 51% larger than non-refundable fares. As expected, variation in fares across flights is very close for both fare types, but non-refundable fares appear to have more within-flight variation than do refundable fares. Table 2 presents the coefficients of a regression of the logarithm of the difference in fares, \( \ln(p^r - p^{nr}) \), on a set of dummies measuring the days to departure (\( \tau \)) with the 1-day-in-advance dummy excluded. Both columns are estimated using flight fixed effects to control for route-, carrier-, and flight-specific characteristics, while the second column additionally controls for capacity utilization using \( LOAD \). The numbers in parentheses are t-statistics based on cluster-robust standard errors, clustered by airline. Column 1 shows that at a 1% significance level, with the exception of 4 days in advance, the price gaps are larger than the gap from 1 day in advance. The decline in the gap appears to occur during the last 13 or 16 days prior to departure, with statistically nonsignificant fluctuations in the gap during earlier dates. The estimates indicate that, for example, the price difference is 211% larger when \( \tau = 7 \) and 298% larger when \( \tau = 16 \). Column 2, when compared to column 1, shows that the percentage gap decline is smaller

\(^{17}\)This estimator has better finite-sample properties than the popular local kernel estimator.
when controlling for capacity utilization.\textsuperscript{18}

[Insert Table 1 here.]

[Insert Table 2 here.]

Table 3 reports the estimation of Equation 13 across various estimators. For comparison purposes, the first column shows the OLS estimates of the pooled regression model. The t-statistics shown in parentheses are based on cluster-robust standard errors, clustered by airline. Exploiting the panel structure of the data, the second column presents the within-flight regression estimates which allows controlling for the time-invariant regressors that affect price dispersion included in Borenstein and Rose (1994) and Stavins (2001) and other route-, carrier-, and flight-specific characteristics. While the signs of the day-in-advance coefficients in both specifications are consistent with a fluctuating difference in earlier dates and a sharp decrease in the gap close to departure, the squared and cubic terms are not statistically significant. However, these estimates, along with the results reported in Table 2, are not controlling for the potential endogeneity of \textsl{LOAD} and the dynamics of cumulative sales and previous prices.

[Insert Table 3 here.]

The third and fourth columns report the two-step first-differenced GMM panel estimator as proposed in Holtz-Eakin et al. (1988) and Arellano and Bond (1991). The t-statistics in parentheses are based on the Windmeijer finite-sample correction for the standard errors of the two-step estimates. The GMM difference panel estimator works by taking first-differences in Equation 13 to eliminate time-invariant characteristics and assumes that the error term, $\varepsilon_{ijt}$, is not serially correlated. Moreover, in this estimation the series $LOAD_{ijt}$ may be endogenous in the sense that $LOAD_{ijt}$ is correlated with $\varepsilon_{ijt}$ and earlier shocks but uncorrelated with $\varepsilon_{ij,t+1}$ and subsequent shocks. Then lagged values of $LOAD_{ijt}$ are valid instruments in the first-differenced equation. Column 3 uses $LOAD_{ij,t-2}$ as an instrument, while column 4 uses $LOAD_{ij,t-3}$ and earlier lags as instruments.\textsuperscript{19} To deal with

\textsuperscript{18}Sweeting (2008) runs a similar specification, but of prices—not a price gap—on a set of dummies to analyze the dynamics of prices in secondary markets for Major League Baseball tickets.

\textsuperscript{19}$\tau_{ijt}$ is considered strictly exogenous in these estimations, since it was selected by the researcher to change every three days from 82 days in advance to 1 day in advance.
the problem that the new error term, $\varepsilon_{ijt} - \varepsilon_{ijt-1}$, is correlated with the lagged dependent variable, $\ln(p_{ijt-2} - p_{ijt-2} - 2 - p_{njt} - 2)$, is also used as an instrument. We find that $\tau$, $\tau^2$, and $\tau^3$ are statistically significant in both GMM difference specifications and that the signs are consistent with a quick decline in the gap close to departure. To address the validity of the specifications, columns 3 and 4 also report two tests. To test the hypothesis that the error term, $\varepsilon_{ijt}$, is not serially correlated, we test whether the differenced error term is second-order serially correlated. The p-values reported for the serial correlation test provide strong support for a valid specification. To test the overall validity of the instruments, we provide a Sargan test of over-identifying restrictions. The validity of lagged levels dated $t - 2$ as instruments in column 3 is rejected. However, it is not rejected for lagged levels dated $t - 3$ (and earlier) as instruments.

Blundell and Bond (1998) point out that, when the explanatory variables are persistent over time, lagged levels of these variables are weak instruments for the regression equation in differences. To reduce the potential bias and imprecision of the difference estimator, we use the system estimator as suggested in Blundell and Bond (1998). Usual weak-instrument tests cannot be implemented in these GMM specifications, so we use the known bias in the difference GMM by comparing its sample performance with the pooled OLS and within-group estimators, which have known properties in dynamic panel data, and see if the system GMM improves the precision of the estimates. This system estimator combines the regression in differences with the regression in levels. The instruments for the regression in levels are the lagged differences of the corresponding variables. The validity of the instruments relies on an additional assumption: There is no correlation between the differences of $LOAD$ and the flight-specific effects, but there may be correlation between the levels of $LOAD$ and the flight-specific effects. Columns 5 and 6 in Table 3 report the two-step system GMM estimator, with the figures in parentheses being t-statistics based in the Windmeijer robust estimator. The serial-correlation test shows strong support for the assumption of no serial correlation, and the Sargan provides strong support for the validity of the instrument list. In addition, the difference Sargan that tests for the additional moment conditions used in the levels equations accepts their validity.

The gap profile as estimated by our preferred specification, column 6, is presented as the solid line in Figure 4 along with the nonparametric partial regression plot, where the
bars represent asymptotic standard errors. Consistent with the dummy variable regression of Table 3, there is a sharp decrease in the gap during the last two to three weeks prior to departure. The gap between $p^r$ and $p^{nr}$ closes as the departure date nears and consumers are more certain about their travel plans. While there does not seem to be much learning during earlier dates, most of the learning takes place during the last two weeks prior to departure.

[Insert Figure 4 here.]

4 Conclusions

This paper shows the importance to airlines of offering a menu of prices namely refundable and non-refundable fares. We show that a monopolistic airline can separate consumers who are uncertain about their demand for travel and have different willingness to pay. The fact that individual demand uncertainty is not fully resolved by the time the individual buys a ticket is used by the seller to price discriminate and extract more surplus. In our model, buyers can use refund contracts to insure against uncertainty in consumption. One implication from the theoretical model is that the gap between refundable and non-refundable fares is a function of the individuals’ travel uncertainty. If there is no uncertainty in individual demand, there is no difference in buying a refundable or a non-refundable ticket, and hence there should be no difference between these two fares.

The empirical section looks at the dynamics of the price gap, refundable minus non-refundable, in 96 monopoly routes and tests whether the individual demand uncertainty implied by the carrier’s pricing strategy is resolved as the departure date approaches. After controlling for unobserved time-invariant flight-, carrier-, and route-specific characteristics, unobserved time-variant seat-specific characteristics, and potential sources of endogeneity, the results show that the theoretical predictions are empirically supported. Second-degree price discrimination in the form of refund contracts shrinks as the departure date nears. Nonlinear parametric specifications and a nonparametric regression show that most of the individual demand uncertainty is resolved during the last two weeks, when the opportunity for price discrimination through refund contracts declines.
References

Appendix

In this appendix we first prove two lemmas that we use to derive the result in Proposition 2 and then we prove the proposition.

**Lemma 1** If $u'' \leq 0$, then $c_\theta \leq \pi_\theta v_\theta$.

**Proof.** We rewrite (3) as

$$-u(-c_\theta) = \frac{\pi_\theta}{u(v_\theta - c_\theta) - u(-c_\theta)}.$$ (14)

We multiply both sides of (14) by $v_\theta/c_\theta$ to obtain

$$-u(-c_\theta)/c_\theta = \frac{\pi_\theta v_\theta}{u(v_\theta - c_\theta) - u(-c_\theta)/v_\theta}.$$ (15)

If $u'' \leq 0$, the left-hand side of (15) $\leq 1$ and, as a result, $c_\theta \leq \pi_\theta v_\theta$.

**Lemma 2** If $u'' \leq 0$, then $m \leq \frac{c_L}{\pi_H}$.

**Proof.** We rewrite (9) as

$$-u(-c_L) = \frac{\pi_H}{u(v_H - c_L) - u(v_H - m)}.$$ (16)

We multiply both sides of (16) by $(m - c_L)/c_L$ to obtain

$$-u(-c_L)/c_L = \frac{\pi_H(m - c_L)}{(1 - \pi_H)c_L}.$$ (17)

If $u'' \leq 0$, the left-hand side of (17) $\leq 1$ and, as a result, $m \leq \frac{c_L}{\pi_H}$.

**Proof of Proposition 2**

Since the airline cannot observe each consumer’s type, the airline may try to set prices so that consumers either pool or separate their strategies. We summarize the consumers’ responses to the airline’s price menu as follows:

- **Pooling 1**: The airline sells refundable tickets to both types (RB).
- **Pooling 2**: The airline sells non-refundable tickets to both types (NB).
– Separating 1: The airline sells only refundable tickets to type $H$ (RH).

– Separating 2: The airline sells only non-refundable tickets to either type $H$ or $L$ (NL if $c_L > c_H$ or NH if $c_L < c_H$).

– Separating 3: The airline sells refundable tickets to type $H$ and non-refundable tickets to type $L$ (RHNL).

We consider these responses under two cases: $c_L \geq c_H$ and $c_L < c_H$. For RB the airline maximizes its profit by setting $p^{nr} \geq \max\{c_H, c_L\}$ and $p^r = v_L$ in both cases. For NB the airline sets $p^{nr} = c_H$ if $c_L \geq c_H$, $p^{nr} = c_L$ if $c_L < c_H$, and $p^r > v_H$ in both cases.

For RH the airline sets $p^{nr} > c_L$ if $c_L \geq c_H$, $p^{nr} \geq c_H$ if $c_L < c_H$, and $p^r = v_H$ in both cases. For NL in case $c_L > c_H$, the airline sets $p^{nr} = c_L$ and $p^r > v_H$. For NH in case $c_L < c_H$, the airline sets $p^{nr} = c_H$ and $p^r > v_H$. Note that NL is not possible when $c_L \leq c_H$ and that NH is not possible when $c_L \geq c_H$.

For RHNL, Proposition 1 states that the airline sets $p^{nr} = c_L$ and $p^r = v_H$ if $c_L \geq c_H$ and $p^{nr} = c_L$ and $p^r = m$ if $c_L < c_H$. The airline’s profits for each response by the consumers in the two cases are summarized in Table 4.

Let $\Pi(\cdot)$ denote the airline’s maximum profit given consumer responses to the airline’s price menu. If $c_L \geq c_H$ we find that $\Pi(RHNL) \geq \Pi(RH)$ and $\Pi(RHNL) \geq \Pi(NL)$. Given that $u'' \leq 0$, Lemma 1 suggests $c_H \leq \pi_H v_H$. Hence $\Pi(RHNL) \geq \Pi(NB)$. If $\frac{N_H}{N_L} \geq \frac{\pi_{L, v_L - c_L}}{\pi_H (v_H - v_L)}$, then $\Pi(RHNL) \geq \Pi(RB)$.

If $c_L < c_H$ $\Pi(RH) \geq \Pi(NH)$ because $c_H \leq \pi_H v_H$. Given that $u'' \leq 0$, Lemma 2 suggests $\pi_H m \geq c_L$. Hence $\Pi(RHNL) \geq \Pi(NB)$. If $\frac{N_H}{N_L} \geq \frac{\pi_{L, v_L - c_L}}{\pi_H (m - v_L)}$, then $\Pi(RHNL) \geq \Pi(RB)$. If $\frac{N_H}{N_L} \leq \frac{c_L}{\pi_H (v_H - m)}$, then $\Pi(RHNL) \geq \Pi(RH)$.

Notes: The dependent variable is $\ln(p_{ij,t-1} - p_{ij,t-1}')$. Columns 2 through 6 control for carrier-, route-, and flight-specific characteristic. t-statistics in parentheses for the OLS and the Within groups based on cluster-robust standard errors, clustered by airline. t-statistics in parentheses for the two-step system GMM based on Windmeijer WC-robust estimator; ***p-value<0.01, **p-value<0.05, *p-value<0.1. a The null hypothesis is that the errors in the first-difference regression exhibit no second-order serial correlation (valid specification). b The null hypothesis is that the instruments are not correlated with the residuals (valid specification). c The null hypothesis is that the additional instruments $t - 3$ are not correlated with the residuals (valid specification).

Table 4: The airline’s profits given consumers’ responses
