We examine the intertemporal relation between government revenue and expenditure in the UK during 1750 to 2004. We pay particular attention to long run trends by applying a battery of unit root and cointegration techniques to the data, and we use a modified Granger causality test on data spans organized around structural breaks in the series. The results suggest that, allowing for structural breaks, UK real revenue and spending are I(1) series and cointegrated and that Granger causality runs from government spending to revenue. As such, the ‘spend-tax’ hypothesis appears to best characterize the long run intertemporal relation between government revenue and spending in the UK.

Keywords: revenue-expenditure nexus; unit roots; cointegration; structural breaks; causality

I. Introduction

There is a substantial empirical literature on the intertemporal relation between government expenditure and revenue in the generation of fiscal deficits.¹ Much of it has focused on whether a ‘causal’ relation exists between revenue and spending and the resulting implication for fiscal consolidation strategies. There are four main hypotheses in this regard. Unidirectional causality from taxation to expenditure (‘tax-spend’) is suggested by Friedman (1978, 2003), who argues that tax cuts generate politically intolerable fiscal deficits that eventually force spending cuts, and that a strategy of raising taxes to reduce fiscal deficits will likely fail because the additional revenues will result in an increase in government expenditure. This pattern of causality is also consistent with Buchanan and Wagner (1977), who argue that tax cuts reduce the perceived cost of government programmes, leading to a greater demand for such programmes, more government spending and larger fiscal deficits. Unidirectional causality from spending

¹Payne (2003) provides a survey of recent studies on the issue.
to taxation (‘spend-tax’) is consistent with Peacock and Wiseman’s (1961, 1979) ‘displacement effect’, which stresses the propensity for government expenditures to increase permanently in the face of temporary developments (such as major wars); and Barro’s (1979) Ricardian equivalence proposition that government borrowing (to finance spending) today results in an increased future tax liability; in these contexts, fiscal consolidation should focus on cutting spending. Bidirectional causality is suggested by the ‘fiscal synchronization hypothesis’ associated with Musgrave (1966) and Meltzer and Richard (1981), who argue that the public chooses simultaneously an optimal package of spending programmes and the taxes necessary to fund the spending. Finally, Wildavsky (1988) and Baghestani and McNown (1994) have advanced an ‘institutional separation hypothesis’ under which decisions on taxation are taken independently from the allocation of government expenditure, such that no causal relation between revenue and spending is to be expected. In the case of bidirectional causality or no causality, whether fiscal consolidation is carried out through tax increases or cuts in spending would not affect the likelihood of the consolidation being successful.

A notable feature of the many associated empirical studies is that they often draw quite different conclusions as to the intertemporal relation between government revenue and spending for the same country. In the UK context, for example, support for a ‘tax-spend’ hypothesis is reported by Koren and Stiassny (1998) during 1956 to 1992, and Chang et al. (2002) for 1951 to 1996; support for a ‘spend-tax’ tax hypothesis is reported by Joulaian and Mookerjee (1991) for 1961 to 1986; and support for a ‘fiscal synchronization’ hypothesis is reported by Hasan and Lincoln (1997) for 1961 to 1993 (quarterly data) and Owoye (1995) for 1961 to 1990. Finally, Ram (1988) finds support for the tax-spend hypothesis for the period 1958 to 1985 using constant price fiscal variables, but support for the fiscal synchronization hypothesis when the variables are expressed in current prices. The differences in these results could be attributed to the differences in the sample periods, model specifications and the choice of econometric methodology. But the reliability of the test results can also be affected by the empirical strategies employed that are based on relatively short data spans and Granger-causality tests or impulse response functions using mainly error-correction and cointegrated Vector Autoregressive (VAR) models. In particular, the validity of causality test results can be questioned when these are formulated on the basis of the outcomes of unit root and cointegration tests that are known to suffer from size and power problems in small samples and are suspect if there is reason to believe that the country has experienced a structural break in its fiscal policies over the sample period (Perron, 2006).

In this article, we contribute to the empirical literature on the intertemporal relation between revenue and spending in the UK in several respects. First, we focus on the historical experience using a data span of more than 200 years, which substantially increases the number of observations used compared to the studies noted above. Second, we take as our point of departure the framework of the government intertemporal budget constraint and fiscal policy sustainability, the most recent literature on which has emphasized flexible testing strategies based on cointegration. Thus, we pay particular attention to long-run trends in the data by applying a battery of unit root tests and cointegration techniques, including tests that allow for structural breaks in the data. The analysis of structural breaks in the context of nonstationarity and cointegration tests provides us with a basis for investigating revenue-expenditure causalities over specific sub-samples where no such breaks are identified. Finally, we report results from a modified Granger-causality test suggested by Dolado and Lütkepohl (1996) applied to data spans organized around structural breaks in the series. Our results suggest that, among the hypotheses discussed above, the ‘spend-tax’ hypothesis appears to be the one that would most accurately characterize the long-run intertemporal relation between government revenue and expenditure in the UK.

The next section of this article provides a brief description of long-run trends in government revenue and expenditure in the UK during 1750 to 2004; the empirical methodology and results are presented in Section III; and concluding observations are summarized in Section IV.

II. The Data and Some Stylized Facts

The choice of specific definitions of fiscal variables varies widely in the empirical literature on the

date spans and Granger-causality tests or impulse response functions using mainly error-correction and

cointegrated Vector Autoregressive (VAR) models. In particular, the validity of causality test results can be questioned when these are formulated on the basis of the outcomes of unit root and cointegration tests that are known to suffer from size and power problems in small samples and are suspect if there is reason to believe that the country has experienced a structural break in its fiscal policies over the sample period (Perron, 2006).

In this article, we contribute to the empirical literature on the intertemporal relation between revenue and spending in the UK in several respects. II. The Data and Some Stylized Facts

The choice of specific definitions of fiscal variables varies widely in the empirical literature on the
relation between government spending and revenue, and the appropriateness depends largely on the objectives of the study (Baghestani and McNown, 1994). The studies whose main focus has been on revenue–expenditure causality have used real or nominal series as well as Gross Domestic Product (GDP) ratios expressed in logarithms; and the VAR models employed in these studies have often included additional macroeconomic control variables (such as GDP growth and inflation). In contrast, studies that have examined the revenue–spending relationship from the viewpoint of fiscal policy sustainability, for which the government’s intertemporal budget constraint has served as an analytical framework, have used mainly levels of real fiscal variables (e.g., Ahmed and Rogers, 1995; Quintos, 1995). As our point of departure is also the government’s intertemporal budget constraint framework, we also employ levels of real fiscal variables in our study.

Annual data for the UK government real revenue, real spending and the fiscal balance for the period 1750 to 2004 are shown in levels and first differences in Fig. 1 (panels A and B, respectively) and natural logarithms of levels and the first differences in Fig. 2 (also panels A and B, respectively).4 Barro (1987) and Clark and Dilnot (2002) have stressed the short-run dominant effect of wars on the UK public finances in the eighteenth and nineteenth centuries and the first half of the twentieth century, whereby wars were typically associated with large increases in public spending and relatively smaller increases in taxation. As noted above, Peacock and Wiseman (1961, 1979) have stressed the enduring effect of the size of government in the UK data, with public spending falling back after the wars but to levels much higher than those that had preceded the war, referring to this as the ‘displacement’ effect. Clark and Dilnot (2002) suggest that the ‘displacement effect’ may occur because wars ease the constraint on politicians’ ability to raise taxes as much as they would like and provide scope for higher levels of non-military spending once war is over. After 1945, the main features of the data on the spending side are the temporary boost from the Korean War in the early 1950s, and two periods of rapid growth in the first half of the 1970s and in the early 1990s, which mainly reflected higher cyclical spending associated with downturns in the economy. In the second half of the 1990s, spending declined as the economy strengthened but picked up again during the last years of the sample period because of a structural increase in social benefits and pension payments (Emmersen et al. 2003). The main features on the revenue side are the sharp increase in the tax burden in the mid-1960s to 1970 and the decline in revenues in the late-1980s to the early 1990s, followed by a rapid increase thereafter.5 Reflecting the above developments, the fiscal position shifted from being generally in deficit in the early part of the sample period to being mainly balanced or in surplus in the period between the Napoleonic War and World War I, and persistently in deficit after the early 1950s. Thus, UK government revenue and spending generally display a high degree of co-movement over the long run, which is suggestive of cointegration, but Figs 1 and 2 make clear that there have been several periods in which the series have diverged markedly, indicating the need to take account of possible structural changes in fiscal policy. Indeed, the data in levels, both with or without logarithmic transformation, show the episodes, mainly coinciding with major wars, where a change in the level of the series and/or in trend could have potentially taken place.

III. Empirical Methodology and Results

In this section, we focus on the time series properties of UK government real revenue and expenditure and present the results of unit root and cointegration tests, including from tests that allow for structural break(s) in the series.

Unit root tests

Three sets of unit root tests are used to examine the stationarity properties of the levels and first difference of the government revenue and spending series. The first set comprises tests that are relatively common in the literature but have been criticized

---

4 The series are from Mitchell (1988) and the Annual Abstract of Statistics published by the UK National Statistics Office (NSO), and were deflated using the consumer price index compiled by O’Donoghue et al. (2004). The data are calendar year; the fiscal data are for the central government and are total revenue and expenditure (including transfers). While the information on the details about the data used in other similar studies is not readily available, some studies have used the Government Finance Statistics or the International Financial Statistics of the IMF, or the Organization for Economic Co-operation and Development (OECD) Economic Indicators as the sources for the data on central government expenditure and revenue.

5 Clark and Dilnot (2002) note that between 1964 and 1970, the increase in UK government revenue was the largest significant and sustained increases in the tax burden in the twentieth century that was not associated with a war or pre-war military build-up.
for their bias towards nonrejection of the null hypothesis of a unit root against the alternative of (trend) stationarity in the presence of structural breaks and low power for near-integrated processes. These are the Augmented Dickey–Fuller (ADF) test developed by Dickey and Fuller (1979) and Said and Dickey (1984); the DF-GLS test developed by Elliot et al. (1996), which is a modified Dickey–Fuller test that has improved power in small samples; and the Phillips and Perron (1988) test.

The second set of tests allows for endogenously determined structural breaks in the series and comprises the Zivot and Andrews (1992) and Lee and Strazicich (2003, 2004) tests. With these tests, the structural breakpoint is determined by utilizing a grid search over a range of possible breakpoints and choosing the year when the unit root \( t \)-statistic is minimized. The former test has been criticized because it does not allow for breaks under the null hypothesis of a unit root, which may bias the test and lead to size distortions in the presence of a unit root with a break and/or loss of power (Nunes et al. 1997; Perron, 2006; Glynn and Perera, 2007). However, the minimum Lagrange Multiplier (LM) unit root test
proposed by Lee and Strazicich (2003, 2004) for one and two breaks allows for breaks under both the null and alternative hypotheses and avoids the problems of bias and spurious rejections of the null hypothesis, with the alternative hypothesis unambiguously implying trend-stationarity.\(^6\) We consider two types of breaks for the Lee–Strazicich test – a level shift and a shift in both level and trend, which corresponds to Perron’s (1989) ‘crash’ Model A (change in level/intercept) and Model C with a simultaneous change in level and growth path, respectively.\(^7\) The data suggest shifts around the World War I and II.

\(^6\) In addition, Zivot–Andrews and other similar ADF-type endogenous break tests tend to select the break point incorrectly (one time period before the true break), where the bias and spurious rejections are the greatest. In contrast, the break point(s) tend to be determined correctly at the true break when using the LM test, with the accuracy increasing with the magnitude of the break(s). But even when the size of the break(s) is small and the break point cannot be accurately estimated, the LM test does not suffer a significant loss of power in this case as this is similar to having no break (Lee and Strazicich, 2003, 2004).

\(^7\) Lee and Strazicich (2003, 2004) do not examine Perron’s (1989) ‘changing growth’ Model B as it is commonly held that most economic time series can be adequately described by model A or C.
In particular a possible level-trend shift for the series in levels and a level shift for the log-levels. We follow the literature and report the results for all four specifications (two models for one and two-break tests each).

The final set of tests allow for an exogenously determined break point, and comprises the test proposed by Saikkonen and Lütkepohl (2001, 2002) and Lanne et al. (2002), with a break given by:

and also around the turn of the nineteenth century for the log-series); in particular a possible level-trend shift for the series in levels and a level shift for the log-levels. We follow the literature and report the results for all four specifications (two models for one and two-break tests each).

The final set of tests allow for an exogenously determined break point, and comprises the test proposed by Saikkonen and Lütkepohl (2001, 2002) and Lanne et al. (2002). This test is based on estimating the deterministic part first under the unit root null hypothesis and then performing an ADF-type test on the adjusted series, including terms to correct for estimation errors in the parameters of the deterministic part. We report the test results when the beginning of World War II is taken (1939) as a break point (though the results remain largely robust to other choices for a break point).8

The results of these different unit root tests for the real revenue and real expenditure series are reported in Table 1 for the levels and first differences of the data and in Table 2 for the natural logarithms of the series. Most of the tests, with and without breaks, suggest that the series in levels behave like unit root processes, while for the first differences the unit root can be strongly rejected; support for the presence of a unit root is particularly strong for the revenue series.9

The tables show that the most frequent break points

---

8 Unit root tests with more than two breaks are often the extensions of the tests that do not allow for break(s) under the null hypothesis of unit root, while such extensions for the Lee–Strazicich type tests are, to our knowledge, not available. Hence, note that some loss of power can be expected from ignoring more than two breaks in the one- or two-break test.

9 This is in line with the findings of Ahmed and Rogers (1995), who use only the Phillips and Perron (1988) and Perron (1989) tests, the latter of which is based on the assumption of a known single structural break (including for the year 1939, for which, however, Ahmed and Rogers reject the unit root null for the tax revenue series).
determined by the unit root tests are associated with war events, including the Anglo-Boer War (1899 to 1902), World War I (1914 to 1918) and World War II (1939 to 1945). We conclude from these results that government revenue and expenditure are integrated

\( I(1) \) provided that structural breaks in the series are taken into account (particularly level shift(s)), and that cointegration analysis of the revenue and expenditure series is appropriate.\(^{10}\)

**Cointegration of revenue and expenditure**

An assessment of the cointegration of UK real revenue and expenditure is needed to determine the appropriate formulation of Granger-type causality tests (Engle and Granger, 1987). We report the results from several types of test in Table 3 (levels of the series) and Table 4 (logarithms of the series). The first type of cointegration tests is the residual-based test of Gregory and Hansen (1996a, b) with one endogenously determined break. Tests are carried out for four cases of a structural change in the cointegrating relation, including a level shift, a level shift with trend, a level shift with a change in the slope coefficient or a regime shift (with no trend) and a regime shift with a trend shift. are reported for the null of no-cointegration against the alternative of cointegration with a break. The results in panel I of Tables 3 and 4 suggest that the series are cointegrated; however, as in the case for the unit root tests discussed above, the value of the break point associated with the minimal value of a given statistic is not, in general, a consistent estimate of the break date if a change is present. Accordingly, in panels II–IV of Tables 3 and 4 we report the results from the tests that are based on a multivariate approach where revenue and spending are modelled by a VAR process. In panel II, we report results from the Saikkonen and Lütkepohl (2000a, b, c) cointegration tests, which involve a Generalized Least Squares (GLS)-type detrending procedures for estimating the trends component of the series for the cases where: (1) there is a linear trend in both the variables and cointegrating relation and (2) there is a trend only in data and not in the cointegrating relation. For each case, specifications with and without level shifts have been considered but only the results without level shifts are presented.

The last two panels in Tables 3 and 4 present the results from the cointegration analysis based on a rank test developed by Johansen et al. (2000), in which government spending and revenue are modelled by a VAR process with one or two breaks in the deterministic component and known break points. When the structural breaks are chosen around the major World Wars, the test results for the VAR in levels appear to suggest that the system is stationary, hence instead of a cointegration analysis, standard

inference would apply (Table 3). However, the limit distribution of the Johansen et al. (2000) test depends on exact specification of the deterministic terms and on the true break dates and, as argued by Lütkepohl et al. (2003), for cases of a VAR process with level shift, size properties of the Johansen et al.-type tests could be unsatisfactory. We also performed the trace tests developed by Johansen (1988, 1991, 1995) with dummy variables to correct for large outliers (mainly in the expenditure series). The model in levels passes only partly the misspecification tests (including the multivariate and univariate residual-based tests) and does not give robust support for cointegration. In general, more robust and stronger cointegration results for all specifications are obtained when the logarithms of the revenue and spending series are used (Table 4). As discussed earlier, the behaviour of the fiscal balance appears to have changed since the early 1950s, which is suggestive of a change in the long-run relation between government revenue and spending. Indeed, when, as a break point, the post-1950 years

are chosen, we find evidence of cointegration particularly when allowing for joint break(s) in level(s) and trend. In turn, pattern that emerged of larger and more slowly reversing fiscal deficits from the 1950s would be consistent with Peacock and Wiseman’s ‘displacement effect’ with regard to government expenditure, the political economy difficulties in maintaining the associated higher levels of taxation that this implied, and the deepening of UK government debt markets which facilitated the financing of fiscal deficits. Not surprisingly, the tests suggest a presence of a strong cointegrating relation between spending and revenue in the sub-samples when the war-related breaks are excluded.

Revenue and expenditure ‘causalities’

The findings from the unit root and cointegration analyses underscore the importance of taking due account of structural breaks when analysing the long-run relation between revenue and expenditure in the UK. Similarly, structural stability is an important condition for standard Granger-causality tests. Lütkepohl (1991), for example, shows that the Granger-causality tests may over-reject the true null condition for standard Granger-causality tests. The Dolado and Lütkepohl (1996) test can be described as follows: let \( y_t = (REV_t, EXP_t)' \) be a VAR\((k)\) cointegrating process for real revenue and expenditure with Vector Error Correction Model (VECM) representation given by

\[
\Delta y_t = \Pi y_{t-1} + \sum_{i=1}^{k-1} \Gamma_i \Delta y_{t-i} + \Phi D_t + \epsilon_t, \quad t = 1, \ldots, T
\]

(1)

where \( \Pi \) (with rank \( r \)) and \( \Gamma \) are coefficient matrices, \( D_t \) the deterministic terms and \( \epsilon_t \) is the error term. For testing whether one variable of the system is Granger-noncausal for the other, the levels VAR form of the model is considered but the test is based on a model with \( k+1 \) lags of the endogenous variables

\[
y_t = \sum_{i=1}^{k+1} \left[ \begin{array}{cc} \alpha_{11,i} & \alpha_{12,i} \\
\alpha_{21,i} & \alpha_{22,i} \end{array} \right] y_{t-i} + \Phi D_t + \left[ \begin{array}{c} \epsilon_{1t} \\
\epsilon_{2t} \end{array} \right] \]

(2)

The null hypothesis that \( REV_t \) is Granger-noncausal for \( EXP_t \) is tested by checking the hypothesis \( \alpha_{21,i} = 0 \) (\( \alpha_{12,j} = 0 \)), \( i = 1, \ldots, k \). In this setup, one can also test for so-called instantaneous causality, which is characterized by nonzero correlation of \( \epsilon_{1t} \) and \( \epsilon_{2t} \), and for which the null hypothesis \( E(\epsilon_{1t}\epsilon_{2t}) = 0 \) is tested against the alternative of a nonzero covariance between the two error vectors.

The Granger-causality test results are reported in Table 5, where panels I and II correspond to the VAR model based on the levels and log-levels of the revenue and spending series, respectively. These tests are based on the cointegrated VAR models specified for each sub-sample, including by: (1) establishing the significance of the deterministic terms and whether these are restricted or unrestricted; and (2) determining the lag order on the basis of the information criteria and checking this with a residual-based analysis focusing on the tests for autocorrelation as well as with the significance of lagged covariates. Despite some differences between the results from the two types of models, the null-hypothesis of non-causality is rejected almost in all cases for the modified procedure, the test performs well if the true order of the process is not known, as is often be the case in empirical studies. Bauer and Maynard (2010) extend this methodology and show that it can provide Granger-causality tests that accommodate stationary, nonstationary, near-stationary, long-memory and unmodelled structural break processes within the context of a single \( \chi^2 \) null limiting distribution.

13 It is well known that in a bivariate cointegrated system there must be Granger-causality in at least one direction (Engle and Granger, 1987).
expenditure series while the opposite is true for the revenue series. The results thus indicate the presence of unidirectional causality from spending to taxation. As such, of the four main hypotheses around which the empirical literature is organized, the ‘spend-tax’ hypothesis associated with Peacock and Wiseman’s (1961, 1979) ‘displacement effect’ and Barro’s (1979) Ricardian equivalence proposition appears to be the one that would most accurately characterize the intertemporal relation between government revenue and expenditure in the UK.

### IV. Conclusions

In this article, we examined the intertemporal relation between government revenue and expenditure in the UK during 1750 to 2005. We have built on the previous studies of the issue by focusing on the UK’s long-run experience with data spanning more than 200 years, paying particular attention to long-run trends in the data by applying a battery of unit root and cointegration techniques, including tests that allow for structural breaks, and by applying a modified Granger-causality test to data spans organized around structural breaks in the series. Most of the unit root and cointegration tests, both with and without breaks, and when applied to the data in levels or natural logarithms of the levels, suggest that allowing for structural breaks, UK real revenue and spending during the period were I(1) series and cointegrated. In addition, the results from the modified Granger-causality tests generally support a pattern of causality running from government spending to government revenue. This is consistent with the long-run intertemporal relation between government revenue and expenditure in the UK being characterized by the ‘spend-tax’ hypothesis associated with Peacock and Wiseman’s ‘displacement effect’ and Barro’s Ricardian equivalence proposition.
