Properties of intercalated $2\text{H-NbSe}_2$, $4\text{Hb-TaS}_2$, and $1\text{T-TaS}_2$ *

S. F. Meyer¹, R. E. Howard, G. R. Stewart, J. V. Acrivos², and T. H. Geballe

Department of Applied Physics, Stanford University, Stanford, California 94305
(Received 16 April 1974)

The layered compounds $2\text{H-NbSe}_2$, $4\text{Hb-TaS}_2$, and $1\text{T-TaS}_2$ have been intercalated with organic molecules, and the resulting crystal structure, heat capacity, conductivity, and superconductivity have been studied. The coordination in the disulfide layers of $2\text{H-NbSe}_2$ was found to be unchanged in the product phase. Resistance minima appear and the superconducting transition temperature is reduced in the $\text{TaS}_2$ complex. Conversely, superconductivity is induced in the $4\text{Hb-TaS}_2$ complex. Corresponding evidence of a large change of the density of states, negative for $2\text{H-NbSe}_2$ and positive for $4\text{Hb-TaS}_2$, was also observed upon intercalation. The transport properties of all the intercalation complexes show a pronounced dependence upon the coordination of the transition metal.

I. INTRODUCTION

The dichalcogenides of niobium and tantalum have been investigated extensively in recent years. They can be prepared in single crystal form rather easily and possess a number of unusual temperature-dependent physical properties.¹ These are likely to be related to the response of the lattice to the two-dimensional-like characteristic of the Fermi surface. This has recently been discovered to lead to the formation of charge-density waves and ultimately superlattices.² In addition, the very interesting reaction wherein atoms and molecules (I) are inserted between the disulfide layers of the dichalcogenides has initiated many studies.³ In the resulting intercalation complex, the conduction electrons are almost constrained to propagate within a single dichalcogenide layer which is only 6 Å thick, yet superconductivity is, in many cases, enhanced. The ability to react correlates roughly with the $pK_a$ value of I.¹ A charge transfer model has been suggested as the stabilization mechanism,⁴ some support for which can be found in x-ray photoelectron spectroscopy⁵ and nuclear magnetic resonance experiments.⁶

The purpose of this work is twofold. To date, the most stable complexes of $\text{TaS}_2$ are for the $2\text{H}$ polytype in which the tantalum atom is coordinated by a trigonal prism of sulfur atoms, as shown in Fig. 1. The first objective of this work was to search for ligands which form the most stable complexes with the $2\text{H}$ polytype so that other, less reactive polytypes of $\text{TaS}_2$ could be intercalated. The $2\text{H}$ polytype forms imperfect crystals owing to the fact that these are grown as a $1\text{T}$ polytype which is then converted to the former by a phase transition, with a concomitant volume change. The intercalation complexes of the other polytypes are expected to produce sufficiently perfect crystals, enabling study of the superconductivity and the expected anisotropy of the transport properties for the second objective of this work. Previous efforts in this laboratory have involved mixed anion crystals $\text{TaS}_2\text{I}_x\text{Se}_{2-x}$.⁷ These, like the selenides, generally form good crystals, and the ease of intercalation possessed by the sulfide crystals is preserved. The above formulas and those used in the rest of this paper refer to trigonal prismatic coordination in the disulfide layer unless designated otherwise.

In the present investigation, as will be evident, we have succeeded in preparing intercalation complexes of $2\text{H-NbSe}_2$ which form more perfect crystals than the isostructural $2\text{H-TaS}_2$. In addition, we have successfully prepared intercalation complexes of semimetallic $1\text{T-TaS}_2$ in which the coordination of the sulfur atoms about the tantalum is octahedral, and also of the interesting $4\text{Hb-TaS}_2$ polymorph, shown in Fig. 1, where successive layers are alternately trigonal prismatic and octahedral $\text{TaS}_2$.⁸ We are thus able to study the effect of forming intercalation complexes upon the metallic and superconducting trigonal layers as well as upon the semiconducting (or semimetallic) octahedral layers.

The paper is organized as follows. In Sec. II the methods of preparation and the methods used to characterize the sample, which are similar to those already in the literature, are briefly stated and discussed. In Sec. III the methods for the measurements of resistivity, superconductivity, and heat capacity which have been made on suitable crystals are presented and discussed. In Sec. IV we discuss the results of the measurements, and in Sec. V draw some experimental conclusions.

II. SAMPLE PREPARATION AND CHARACTERIZATION

The dichalcogenide crystals were prepared from reacted powders using the iodine vapor transport method, as reported elsewhere.⁹ The structures of the principal polymorphs grown, shown in Fig. 1, were verified by x-ray diffraction methods. Neat (reagent grade) chemicals were used for sample preparation. Reagents, such as $\text{NH}_3$, were stored over sodium as liquids under pressure, and the gas handled in a high vacuum system, as reported elsewhere.¹⁰ The reactants (TX₂ crystals and ligands) were sealed in glass ampoules, and dry helium was added to ensure thermal equilibrium during low temperature measurements. The sealed ampoules were reacted at a sufficiently high temperature for intercalation to occur (defined as $T_{\text{inter}}$ in Table I), but not necessarily the lowest possible temperature. The course of the reaction could, in many cases, be qualitatively followed visually simply by observing the marked swelling of the crystals. In those cases (NbSe₂) where the superconducting transition decreased upon intercalation, the transition temperature could be used to monitor the reaction. The superconducting transition was determined with the samples remaining inside the sealed reaction tubes containing an excess of the ligand.

The intercalation complexes prepared and charac-
Amine and also triethylamine appear to form stable complexes at room temperature with 4Hb-TaS₂ properties as heat capacity and resistivity. Ethylenediamine of the organic ligand complexes. For room temperature gravimetric analysis (TGA) on the EDA complexes gases, such as NH₃, a manometric method was used. This stability allowed measurements to be made of such properties as heat capacity and resistivity. Ethylenediamine and also triethylamine appear to form stable complexes at room temperature with 4Hb-TaS₂.

Stoichiometry measurements were difficult for most of the organic ligand complexes. For room temperature gases, such as NH₃, a manometric method was used. The sample was frozen and placed in a manometer system of known volume. The excess liquid was boiled off under vacuum with the sample maintained at a temperature where the sample was stable. This temperature is noted as T_{stable} in Table I and does not imply that it is necessarily the highest stable temperature. When dry, the product was allowed to warm up above θ_{intercalation} in order to reverse the intercalation reaction, i.e., "deintercalate." The pressure measurement allowed the calculation of the mole ratio to about 20% accuracy. The accuracy of this measurement was less for methylamine and ethylamine because of adsorption on the sample surface.

In the case of EDA, a standard weight gain method with results accurate to ±10% was used since the excess reagent could be washed off with isopropanol. Thermogravimetric analysis (TGA) on the EDA complexes showed weight loss at several successive stages, starting at about 50°C and finishing at 400°C. The calculated stoichiometry from the total weight loss exceeded the weight gain during intercalation. This excess weight loss indicates that there exists a large binding energy leading to a destructive deintercalation. This might also be due to the rather high temperatures involved in the TGA.

The crystal structure parameters were obtained using a low temperature x-ray mount and a low temperature sample preparation technique. The x-ray slides were prepared in a nitrogen atmosphere on a working table held at T_{stable}. Slides were stored and transported under liquid nitrogen, including transferal to the low temperature mount of a Picker planar x-ray diffractometer.

Two experiments established that the coordination of the TaS₂ layers does not change in the intercalation process. The original 1T-TaS₂ phase is stable above 700°C, the 4Hb-TaS₂ between 500 and 700°C, and the 2H-TaS₂ below about 450°C. The 1T and 4Hb phases may be obtained by quenching them from the high temperature growth zone where they are stable down to room temperature merely by removing the quartz tubes from the furnace. The possibility always exists in a metastable system that the crystal will transform to the stable 2H phase upon intercalation. The sequence of x-ray diffraction spectra shown in Fig. 2 was carried out to verify that the 4Hb coordination remains after the intercalation reaction and the subsequent deintercalation. It follows from the presence of the (105) line in Fig. 2c, as well as the values of the a and c parameters, that this is still the 4Hb structure. Ethylamine was chosen for this experiment since samples made with it show the least degradation after deintercalation.

A similar sequence, shown in Fig. 3, was used to show that the 1T-TaS₂ coordination does not transform with intercalation. The sample was deintercalated under vacuum at 150°C for 5 min. The deintercalated sample remains in the 1T phase, as shown by the x-ray diffraction in Fig. 3 and from the a and c parameters.

Intercalation is normally accompanied by a shift of the lateral registry of the layers. The absence of the (100) and the intensity distribution of the (10') and (11') diffraction lines in Figs. 2b and 3b indicate that the TX₂ layers are shifted by a/√3 relative to each other along (1120) plane. A study of the intensity distribution yielded the most probable structures, shown in Fig. 4, for 2H-, 4Hb-, and 1T-TaS₂ intercalated with ammonia and EDA. However, Patterson intensity analyses have not been carried out.

The crystal field produced by the sulfur atoms in the intercalated layers of the 2H and 4Hb complexes is trigonal prismatic. This similarity suggests that the bonding interaction is the same in these complexes. The crystal field produced by the sulfur atoms in 3R-TaS₂(EDA)₄ is octahedral, as shown in Fig. 4, and is similar to intercalated compounds of 1T-TaS₂ and of alkali metals in 1T-ZrS₂ and 1T-TiS₂. In this structure the transition element faces a chalcogen across the van der Waals gap.

The crystal structure parameters of NbSe₂ cyclopentadienyl complex were difficult to obtain owing to a serious degradation by the amine, resulting in very broad lines and several c spacings. Of three samples studied, only the one reported in Table I had a sufficiently well-defined c spacing to allow analysis.

III. METHOD OF MEASUREMENT

Superconductivity was detected by measuring the response to an applied ac field. The susceptibility appara-

bolometer to a reference block with about a three-second time constant. To measure \( C_v(T_0 + 0.01 \, ^\circ K) \), where \( T_0 \) is the reference block temperature, the sample temperature is incremented 0.02 °K above that of the block, and then allowed to decay. A Nicolet 1070 signal averaging computer measures this exponential decay, and an on-line PDP-8/e computer calculates the time constant of the decay. The total heat capacity is then calculated using the known thermal conductivity of the wires. The sample heat capacity is derived from the measured total heat capacity by subtraction of the heat capacity of the bolometer and grease. The measured parameters in the Debye–Sommerfeld relation \( C = \gamma T + \beta T^3 \) are given in Table III. The samples used in this experiment were in the 15–25 mg range, with a typical instrumental ad-dendum of about 1% of the total heat capacity at 1 °K and 25% at 5 °K. The deviation in the data was ± 2% or less. The accuracy of the calorimeter has been established by comparison with standard germanium with reproducible results within ± 2%. \(^{20}\)

IV. RESULTS AND DISCUSSION

A. Superconductivity

The highest transition temperature observed in the dichalcogenides is that of NbSe\(_2\), as can be seen in Table I. The NbSe\(_2\) intercalation complexes show either no superconductivity above 0.35 °K (EDA) or \( T_c \)'s markedly below the 7.2 °K \( T_c \) of NbSe\(_2\). The original 4Hb-TaS\(_2\) transported crystals showed quite broad transitions into the superconducting state as measured by ac suscep-tibility, typical of what is frequently observed when connected filaments of a minor superconducting phase are imbedded in a major nonsuperconducting phase. If the distribution of the minor phase is topologically suitable, filamentary superconductivity can provide complete flux exclusion and thus give a full in-phase signal when as little as ~ 1 at.\% of the minor phase is present. However, the minor phase can contribute to the heat capacity only in proportion to its atomic fraction. No sign of superconductivity was detected in the heat capacity of 4Hb-TaS\(_2\) crystals down to 1.1 °K. However, the intercalation complexes have transitions varying up to 5 °K, as given in Table I. The 2H polymorphs of TaS\(_2\) and TaSe\(_2\) are each seen to increase in \( T_0 \) by about a factor of 6 to 4.7 and 0.95 °K, respectively, upon formation of the EDA intercalation complex.

B. Resistivity

The temperature dependence of the resistivity has been investigated for three of the layered materials studied here. Table III summarizes the room temperature resistivities and anisotropies as well as the residual re-

![Fig. 2](image1.png)

**FIG. 2.** X-ray study of 4H-TaS\(_2\) showing spectra for 28°<2θ<65° for (a) 4Hb-TaS\(_2\), (b) 4H-TaS\(_2\) (EtA)\(_{1\frac{1}{2}}\), and (c) deintercalated 4H-TaS\(_2\) (EtA)\(_{\frac{1}{2}}\) showing return to the 4Hb-TaS\(_2\) structure by the presence of \((105)\) and the \( a \) and \( c \) parameters. The incomplete deintercalation of (c) is shown by the remnant of intercalation \((00\, 16)\) to the left of \((105)\) and by the width of the \((00\, 16)\) lines.

![Fig. 3](image2.png)

**FIG. 3.** X-ray study of octahedral TaS\(_2\) showing spectra for 25°<2θ<60° for (a) 1T-TaS\(_2\), (b) 3R-TaS\(_2\) (EDA)\(_{1\frac{1}{4}}\), and (c) deintercalated 3R-TaS\(_2\) (EDA)\(_{\frac{1}{2}}\), showing return to 1T-TaS\(_2\) by the \( a \) and \( c \) parameters. Incomplete deintercalation is shown by the line width.
Meyer, Howard, Stewart, Acrivos, and Geballe: Intercalated 2H-NbSe₂, 4Hb-TaS₂, and 1T-TaS₂

In Fig. 4, 4Hb-TaS₂ is compared with 4H-TaS₂(EDA)₁⁄₄. In contrast to NbSe₂, 4Hb-TaS₂ shows a clear difference between the temperature dependence of ρᵣ and ρₑ. The changes introduced by intercalation are (1) an increase in ρₑ by almost two orders of magnitude, and (2) a suppression of the structure in the resistivity below 100 °K in ρₑ, although the shoulder is still present in the complex. Irreversible effects in 4H-TaS₂(EDA)₁⁄₄ prevented resistivity measurements above room temperature from being used to investigate the transition observed in the unintercalated material at 315 °K.

Intercalation of EDA into 1T-TaS₂ has a very pronounced effect on the temperature dependence of ρₑ, shown in Fig. 7. The 1T phase shows transitions in the resistivity, a metal–semiconductor transition at 350 °K, and a semiconductor-to-semiconductor transition at 190 °K. We observed that the resistivity of 3R-TaS₂(EDA)₁⁄₄ shows the low temperature transition has been suppressed by intercalation, while the high temperature transition has only moved to a slightly lower temperature of 330 °K. The coincidence of magnitudes of resistivities at low T and 330 °K in the original phase and in the complex is striking. However, below 10 °K the resistivity of the complex becomes temperature independent, while that for the 1T-TaS₂ continues to rise.

C. Heat capacity

The data for the systems given in Table III show that the trend already observed in 2H-TaS₂ of a pronounced decrease in the Debye temperature, θ_D, upon intercalation is also present. This increase in the lattice heat capacity has been attributed at least in part to the low energy degrees of freedom associated with the intercalated organic layer. Onset of a T² behavior of C is observed at a lower temperature for the complex than for the parent phase.

In the 2H-NbSe₂ and 4H-TaS₂ systems, γ and Tc change in the same direction. The McMillan formulation of the theory of superconductivity for strong coupled superconductors provides some insight into the physical properties. The decrease in ρₑ/ρᵣ, defined in Table III, with intercalation in 2H-NbSe₂ is consistent with the decrease in dp/dT shown in Fig. 5.

It is possible that the disappearance of portions of the Fermi surface upon superlattice formation in 1T

*The McMillan formalism was derived to fit the experimental data for transition metal superconductors using the measured phonon spectrum of niobium, according to Refs. 13 and 22. The accuracy of this calculation for layered materials is therefore open to question. The analog of the BCS equation for $T_c$ is given by

$$T_c = \frac{\theta_D}{1.45} \exp \left[ -\frac{1.04}{\lambda - \mu^* (1 + 0.62\lambda)} \right],$$

or inverted form

$$\lambda = \frac{1.04 + \mu^* \ln(\theta_D/1.45 T_c)}{(1 - 0.62\mu^*) \ln(\theta_D/1.45 T_c) - 1.04},$$

where $\mu^*$ is the screened Coulomb repulsion, and $\lambda$ the electron-phonon coupling constant. $\lambda$ is given by $\lambda = N(0)(\bar{t})/M(\omega_0^2)$, where $N(0)$ is the band structure density of states, $\bar{t}$ an average of the electron-phonon matrix elements, and $\omega_0^2$ an effective, average phonon frequency. The electronic coefficient of the specific heat is renormalized by $1 + \lambda$ and related to the density of states by $\gamma = \frac{3}{2} \pi \frac{e^2}{m^*} \ln(\theta_D/1.45 T_c) N(0)$. Values of $\lambda$ were calculated with an assumed value of $\mu^* = 0.15$, as suggested by McMillan for transition metal superconductors.

$\rho$ from ac susceptibility measurement.

*For two of the materials, only upper limits can be placed on $T_c$, leading to an upper limit for $\lambda$. Using the upper limit, and assuming a lower limit of $\lambda = 0$, the range for $N(0)$ can be calculated.

and 4Hb-TaS$_2$ is responsible for their small $\gamma$ values. The $\gamma$ observed for the 4Hb polymorph (Table III) is smaller than the average of the 1T and 2H polymorphs.

FIG. 5. Resistivity of 2H-NbSe$_2$(ED) and 2H-NbSe$_2$ from Ref. 21 normalized to unity at 273 K. $\rho_0$ for NbSe$_2$ are proportional.

Since the 4Hb polymorph consists of a combination of the 1T and 2H polymorphs, in the limit of zero interaction between adjacent layers one would expect...
various physical quantities for 4Hb-TaS$_2$ to correspond to an average of those for the 1T and 2H phases. The $a$-axis spacing for the 4Hb phase is exactly the mean of that of the parent phases (Table I), while the relative $c$-axis spacing is closer to that of the 1T phase. Freshly transported crystals of 4Hb-TaS$_2$ showed filamentary superconducting transitions as measured by ac susceptibility between 1 and 4 K in nearly all cases, as already discussed. The heat capacity did show a positive deviation from the conventional linear heat capacity plot of $C/T$ vs $T^2$ as the temperature decreased below 3 K. A similar deviation has been observed below 2 K in 1T-TaS$_2$, which of course has no superconducting transition. An applied magnetic field of 8 kG has no apparent effect in either case. The deviation could be accounted for by a small concentration ($< 0.1\%$) of paramagnetic centers perhaps associated with imperfections in the crystals.

The heat capacity of two samples of 4H-TaS$_2$(EDA)$_{1/4}$ is shown in Fig. 8. Three pertinent observations are made. (1) The values of $\gamma$ for the intercalated compound increases more than a factor of 2 (Table III) and is comparable with that of an intercalation complex of 2H-TaS$_2$ with a corresponding $T_c$. (2) A broad anomaly is observed centered around 3.2 K indicating the formation of a condensed, superconducting state. The width of the transition, of the order of 0.5 K, is comparable to widths for other intercalated TaS$_2$ complexes. However, the size of the jump in the heat capacity is smaller than previously observed in the 2H-TaS$_2$ complexes.$^{22}$ (3) An extrapolation of the heat capacity below $T_c$ to zero temperature in the one sample for which more than two points are available indicates a nonzero intercept. An explanation for the finite intercept would be that a fraction of the sample remains normal below $T_c$ because it is not complexed with the EDA. However, we reject this explanation because a fraction greater than 20% of the sample would have to be unintercalated to account for the size of the finite intercept at $T = 0$, and only one phase is observed in x-ray diffraction.

V. CONCLUSIONS

The experimental observations lead to the following conclusions:
(1) A charge transfer model does qualitatively account for the stability of the complexes studied. The stabilization of a Mulliken electron donor--acceptor complex is due to the admixture of excited charge transfer configurations into the ground covalent configuration. For a given ligand, the variation in binding energy and therefore stability is primarily due to the properties of the dichalcogenide. A comparison of $T_{\text{stable}}$ shown in Table I clearly shows that for all compounds studied, 2H-TaS$_2$ was more stable than 4H-TaS$_2$ and 2H-NbSe$_2$. In all cases, the complexes are stable in the presence of excess liquid in equilibrium with the vapor, but only the 2H phase complexes are sufficiently stable at room temperature to resist changes in entropy which favor deintercalation. The relative thickness of intercalated NH$_3$ layers is given by the parameter $\delta$ in Table I. In the NH$_3$ complexes, $\delta$ is approximately 10% greater for 4H-TaS$_2$(NH$_3$)$_2$ than for 2H-TaS$_2$(NH$_3$)$_2$. This contraction of the intercalate layer in the more stable complex is consistent with a higher binding energy in the charge transfer model.

(2) When minima in $\rho_c$ and $\rho_x$ vs $T$ are observed, the superconductivity is suppressed to below 0.35 K. Such minima have been observed in NbSe$_2$(EDA)$_{1/4}$ and also in 4H-TaS$_2$Se$_{0.4}$Se$_{0.6}$ (amine)$_{1/4}$. The fact that Thompson$^{25}$ found a resistance minimum in specially treated TaS$_2$(pyridine)$_{1/4}$ along the c axis but not in the a axis, and also found the superconductivity to remain, can be attributed to the huge anisotropy and two-dimensional character of the complex. The occurrence of a resistance minimum is frequently associated with Kondo (spin-dependent) scattering, which also tends to destroy superconductivity. While it is unlikely that paramagnetic impurities are causing the Kondo scattering, the possibility that a small fraction of bonds are broken by chalcogen extraction during the intercalation process and are turned into defects capable of Kondo scattering cannot be ruled out. A number of other more speculative mechanisms deserve further investigation. A phonon-assisted, hopping conductivity$^{30}$ through the intercalate layer is an intrinsic mechanism that could result in a low temperature minimum in the resistivity. Another possibility is that there may be some instability driven by a Fermi wave vector of the type observed at higher temperatures in nonintercalated compounds. Such instabilities can give charge density waves which can grow with decreasing temperature.

(3) The increase in $\rho_c$ upon intercalation of 4Hb-TaS$_2$ can be explained by the model of tunneling through a barrier. The resistivity of 4Hb-TaS$_2$ complexes in Fig. 6 does not appear to be dominated by mixing the resistivities, as occurs in NbSe$_2$(EDA)$_{1/4}$ and TaS$_2$(pyridine)$_{1/4}$. The relatively temperature-independent conductivity suggests that the dominant conduction mechanism in 4Hb-TaS$_2$ in $\rho_c$ is due to tunneling. A tunneling conductivity involves a transition probability

$$P \sim \exp(-2\mu \delta)$$

leading to a resistivity of the form

$$\rho_c \sim \exp(2\mu \delta)$$

with a barrier height given by $h^2/2m$. The observed change in $\rho_c$ upon intercalation of 4Hb-TaS$_2$ is a factor of 50. A lattice expansion of $\delta = 3.5$ Å leads to a characteristic tunneling length $l^2 \sim 1.7$ Å. The effective mass is not known; however, an $\sim 2$ eV barrier is reasonable for tunneling through a dielectric medium. Confirmation of the nature of the conductivity would involve experiments such as resistivity under pressure to observe the exponential dependence.

(4) The fact that the phase transition in 1T-TaS$_2$ at 350°K is not greatly affected by the separation and lateral translation of the disulfide layers upon intercalation suggests that the transition is an intralayer transition, perhaps involving the formation of superlattices within each layer. The disappearance of the transition at 190°K suggests a dependence upon interlayer coupling.

(5) The apparent finite intercept of $C / T$ vs $T^2$ observed for the 4Hb-TaS$_2$(EDA) complexes in Fig. 8 is suggestive of gapless superconductivity. Since $\rho_c$ and $\rho_x$ in the 4Hb complexes are not dominated by shorts, there could be normal Bloch states in the superconducting energy gap for electrons constrained to propagate in the octahedral layers.

Finally, (6) the formation of charge transfer NbSe$_2$ complexes can explain the observed reduction in $T_c$, Band structure calculations$^{31,32}$ show that the Fermi level lies near a very sharp peak in the density of states; the calculations are supported by the photoemission spectroscopic results$^{33,34}$ which show $N(0)$ decreasing rapidly with energy at the Fermi level. Changes produced by intercalation on the joint density of states have been made evident by the shifts observed in the optical absorbancy peaks when NbSe$_2$ intercalated complexes are formed. Therefore, the finite perturbation introduced by the ligands, which leads to the reduction of $T_c$, must decrease $N(0)$.

ACKNOWLEDGMENTS

We wish to thank Dr. R. E. Schwall for making his specific heat data available to us prior to publication. Also, we thank A. Carpenter and C. Staar for their help in the laboratory.

Meyer, Howard, Stewart, Acrivos, and Geballe: Intercalated 2H-NbSe₂, 4Hb-TaS₂, and 1T-TaS₂

It is true that cyclopropylamine complexes of NbSe₂ and TaS₂ are already known [S. F. Meyer, T. H. Geballe, and J. V. Acrivos, Bull. Am. Phys. Soc. 17, 519 (1972); S. F. Meyer, Ph.D. dissertation, Stanford University, 1973 (unpublished)]. However, solvents, such as dichloromethane, will extract cyclopropylamine from NbSe₂, indicating that it is not tightly bound. EDA is not extracted from the complex by any solvent yet tried.
