ABSTRACT

We present a robust measurement and analysis of the rest-frame ultraviolet (UV) luminosity function at $z = 4$ to 8. We use deep Hubble Space Telescope imaging over the CANDELS/GOODS fields, the Hubble Ultra Deep Field and the Hubble Frontier Field deep parallel observations near the Abell 2744 and MACS 0416.1-2403 clusters. The combination of these surveys provides an effective volume of $0.6-1.2 \times 10^5$ Mpc$^3$ over this epoch, allowing us to perform a robust search for bright ($M_{UV} < -21$) and faint ($M_{UV} = -18$) galaxies. We select galaxies using a well-tested photometric redshift technique with careful screening of contaminants, finding a sample of 7446 galaxies at $3.5 < z < 8.5$, with $>1000$ galaxies at $z = 6 - 8$. We measure both a stepwise luminosity function for galaxies in our redshift samples, as well as a Schechter function, using a Markov Chain Monte Carlo analysis to measure robust uncertainties. At the faint end our UV luminosity functions agree with previous studies, yet we find a higher abundance of UV-bright galaxies at $z > 6$. Our best-fit value of the characteristic magnitude $M^*_{UV}$ is consistent with $-21$ at $z = 5$, different than that inferred based on previous trends at lower redshift. At $z = 8$, a single power-law provides an equally good fit to the UV luminosity function, while at $z = 6$ and 7, an exponential cutoff at the bright-end is moderately preferred. We compare our luminosity functions to semi-analytical models, and find that the lack of evolution in $M^*_{UV}$ is consistent with models where the impact of dust attenuation on the bright-end of the luminosity function decreases at higher redshift, though a decreasing impact of feedback may also be possible. We measure the evolution of the cosmic star-formation rate (SFR) density by integrating our observed luminosity functions to $M_{UV} = -17$, correcting for dust attenuation, and find that the SFR density declines proportionally to $(1+z)^{-4.3\pm 0.5}$ at $z > 4$, consistent with observations at $z > 9$. Our observed luminosity functions are consistent with a reionization history that starts at $z \geq 10$, completes at $z > 6$, and reaches a midpoint ($\chi_{HI} = 0.5$) at $6.7 < z < 9.4$. Finally, using a constant cumulative number density selection and an empirically derived rising star-formation history, our observations predict that the abundance of bright $z = 9$ galaxies is likely higher than previous constraints, though consistent with recent estimates of bright $z \sim 10$ galaxies.

Subject headings: early universe — galaxies: evolution — galaxies: formation — galaxies: high-redshift — ultraviolet: galaxies

1. INTRODUCTION

The past half-decade has seen a remarkable increase in our understanding of galaxy evolution over the first billion years after the Big Bang, primarily due to the updated near-infrared capabilities of the Hubble Space Telescope. Robust galaxy samples at $z > 6$ now include more than 1000 objects (e.g., Bouwens et al. 2010; Oesch et al. 2010a, 2010b; Finkelstein et al. 2010; McLure et al. 2010; Bunker et al. 2010; Finkelstein et al. 2012); Yan et al. 2012; Oesch et al. 2012) with a few candidate galaxies having likely redshifts as high as 10 (e.g., Bouwens et al. 2011a, Ellis et al. 2013, McLure et al. 2013, Oesch et al. 2013, Coe et al. 2013; Oesch et al. 2014; Bouwens et al. 2014). These galaxies are selected photometrically, primarily based on a sharp break at rest-frame 1216 Å due to absorption by intervening neutral hydrogen in the intergalactic medium (IGM).

Studies of galaxies at $z > 6$ have revealed a number of
interesting results. Galaxies at $6 < z < 8$ appear to have bluer rest-frame ultraviolet (UV) colors than at lower redshift, likely due to a decrease in dust attenuation, although the brightest/most massive galaxies do appear to have comparable dust attenuation at $z = 4–7$ (e.g., Finkelstein et al. 2010; Bouwens et al. 2010b; Finkelstein et al. 2012b; Dunlop et al. 2013; Bouwens et al. 2013). Lower mass galaxies have colors consistent with stellar populations harboring significant metal content (though likely sub-Solar), thus the currently detectable populations of galaxies are not dominated by the primordial first generation of stars (e.g., Finkelstein et al. 2012b; Dunlop et al. 2012, 2013). The structures of these galaxies are resolvable, though they show small sizes with half-light radii $\leq 1$ kpc, consistent with the evolution previously detected at lower redshifts (e.g., Ferguson et al. 2003; Oesch et al. 2010a; Ono et al. 2013). Finally, the abundance of these galaxies appears to account for the necessary photons to completely reionize the intergalactic medium (IGM) by $z \sim 6$, and perhaps as high as $z = 7–8$ if one assumes that galaxies at least 5 magnitudes below the detection limit of HST exist (e.g., Finkelstein et al. 2012a, Robertson et al. 2013).

One of the key measurements is the galaxy rest-frame UV luminosity function (hereafter referred to as the luminosity function), as it is one of the most useful tools to study the evolution of a galaxy population. This measure encapsulates the relative abundances of galaxies over a wide dynamic range in luminosity. As the UV light probes recent star-formation activity, the integral of the rest-UV luminosity function provides an estimate of the cosmic star-formation rate density (e.g., Madau et al. 1996; Bouwens et al. 2012; Madau & Dickinson 2014), although this measurement is reliant on dust corrections. The luminosity function is typically parameterized with a Schechter (1976) function with a power-law slope at faint luminosities, and an exponentially declining form at the bright end. Comparing the shape of the luminosity function to the underlying dark-matter halo mass function, previous studies have found that the luminosity function at $z < 6$, when normalized to the halo mass function at the characteristic magnitude $M^*_{UV}$, lies below the halo mass function at both bright and faint luminosities. This is generally assumed to be due to feedback: dominated by accreting supermassive black holes at the bright end (active galactic nuclei: AGN), and by supernova or radiative-driven winds at the faint-end (e.g., Somerville et al. 2008). Dust extinction can also play a role, particularly if the level of attenuation is dependent on a galaxies stellar mass or UV luminosity (e.g., Finkelstein et al. 2012b; Bouwens et al. 2013). Although luminous AGN are present at $z = 6$ (e.g., Fan et al. 2006), they are exceedingly rare, and to date only a single quasar has been observed at $z \geq 7$ (Mortlock et al. 2011). Therefore one may expect the degree of the exponential decline at the bright end to become weaker with increasing redshift. In addition, robustly quantifying the bright end of the luminosity function can allow us to gain physical insight into how these distant galaxies turn their gas into stars, as the star-formation timescale is a significant fraction of the age of the universe, therefore enough time has not yet elapsed for feedback to bring these galaxies into equilibrium. A change in the star-formation timescale is therefore more readily apparent in the shape of the bright end of the luminosity function (e.g., Somerville et al. 2012).

Thanks to the combination of observations from GALEX and the Hubble Space Telescope estimates of the UV luminosity function exist now from $z < 1$ (Arnouts et al. 2005; Cucciati et al. 2012) out $z \geq 8$ (e.g., Bouwens et al. 2007; McLure et al. 2009; Bouwens et al. 2011b; Oesch et al. 2012, 2013; Lorenzoni et al. 2013). Earlier works have concluded that $M^*_{UV}$ declines from around $-21$ at $z = 3$ to fainter than $-20$ at $z = 8$, with the faint-end slope $\alpha$ becoming steeper over this same redshift range (e.g., Bouwens et al. 2007; Reddy & Steidel 2009; Bouwens et al. 2011b; McLure et al. 2013; Schenker et al. 2013). However, in order to adequately quantify the amplitude and form of the bright end, large volumes need to be probed, as bright sources are relatively rare. This has been accomplished via a combination of ground and space-based surveys at $z \leq 6$, with a variety of studies showing conclusively that a single power law does not fit the data, and that some sort of cut-off is needed at the bright end (e.g., Arnouts et al. 2005; Bouwens et al. 2007; Reddy & Steidel 2009; McLure et al. 2009). Although previous luminosity functions have been published at $z \geq 6$, the space-based studies have been based on small volumes (e.g., Bouwens et al. 2011b), and thus, while they can somewhat constrain the faint-end slope, they do not have the capability to constrain the bright end.

Recent studies are starting to make progress at the bright-end. Finkelstein et al. (2013), while selecting galaxies for spectroscopic followup in the GOODS-N field, found an over-abundance of bright galaxies at $z = 7$. Ono et al. (2012) found a similar result, with their discovery of the $M^*_{UV} = -21.8$ galaxy GN-108036 at $z = 7.2$ in GOODS-N. Likewise, Hathi et al. (2012) found two bright $z > 6.5$ candidate galaxies in a ground-based near-infrared survey of GOODS-N. Thus, it appears that the abundance of galaxies at the bright end of the luminosity function may not be decreasing towards higher redshift as previously thought. Although these studies were based in a single field, further evidence comes from Bowler et al. (2014), who used new deep ground-based near-infrared imaging from the UltraVISTA survey (McCracken et al. 2012) to discover 34 luminous $z \sim 7$ galaxy candidates over 1.65 deg$^2$. They combined these galaxies with the results from McLure et al. (2013), which included deep and wide HST imaging over 300 arcmin$^2$ in the GOODS-S, UDS and HDF fields, to analyze the rest-frame UV luminosity function at $z = 7$. They concluded that they did see evidence for a drop-off in the luminosity function at the bright end, however, the drop-off was less steep than that predicted by a Schechter function, leading them to postulate that the $z = 7$ luminosity function has the shape of a double-power law, perhaps similar to that of the possible form of far-infrared luminosity functions (Sanders et al. 2003; Casey et al. 2014).

In this study, we measure the rest-frame UV luminosity function at $4 < z < 8$ with solely space-based data, using the largest HST project ever, the Cosmic Assembly Near-infrared Deep Extragalactic Legacy Survey (CANDELS; PIs Faber & Ferguson). The large area observed by CANDELS allows us to probe large volumes of the distant universe for the rare, bright galaxies. With these data, we investigate the form of the bright-end of the luminosity function and the implications on galaxy evolution. In addition to the deep data in the HDF, we use the CANDELS data in the GOODS-S and GOODS-N fields, which have not only deeper near-infrared imaging, but also imaging in more optical and near-infrared filters than the other three CANDELS fields (UDS, EGS and COSMOS). We also include in our analysis the parallel fields from the first year dataset of the Hubble Frontier Fields, near the Abell 2744 and MACS J0416.1-2403 galaxy clusters. The combination of these data allows us to select a large sample of nearly
7500 galaxies, over a wide dynamic range in UV luminosity at $z = 4–8$ (Figure 1).

This paper is organized as follows. In § 2 we discuss the imaging data used and the catalog construction, and in §3 we present our sample selection via photometric redshifts, and estimates of the contamination. In § 4 we highlight our completeness simulations, and in § 5 we discuss the construction of the rest-UV luminosity function at $z = 4, 5, 6, 7$ and 8. In § 6 we discuss the implications of our luminosity function results, while in § 7 we compare our results to semi-analytical models. In § 8 we present our measurements of the cosmic star-formation rate density, and in § 9 we discuss the implications for galaxies at higher redshifts. Our conclusions are presented in § 10. Throughout this paper we assume a WMAP7 cosmology (Komatsu et al. 2011), with $H_0 = 70.2 \text{ km} \text{s}^{-1} \text{Mpc}^{-1}$, $\Omega_M = 0.275$ and $\Omega_{\Lambda} = 0.725$. All magnitudes given are in the AB system (Oke & Gunn 1983).

2. OBSERVATIONS AND PHOTOMETRY

2.1. Imaging Data

Studying galaxies in the early universe requires extremely deep imaging, necessitating space-based data. Additionally, to probe a large dynamic range in luminosities, we need to combine deep studies over small areas with larger-area surveys with shallower limiting magnitudes. Our study used imaging data from a number of surveys covering both the Northern and Southern fields from the Great Observatories Origins Deep Survey (Giavalisco et al. 2004), with both the Hubble Space Telescope (HST) and the Spitzer Space Telescope. The deepest imaging comes from three surveys of the Hubble Ultra Deep Field (HUDEF): the original HDF survey which obtained optical imaging with the Advanced Camera for Surveys (ACS, Beckwith et al. 2006); and the more recent HUDF09 (PI Illingworth; e.g. Bouwens et al. 2010a; Oesch et al. 2010b) and UDF12 surveys (PI Ellis; Ellis et al. 2013; Koekemoer et al. 2013), which obtained near-infrared imaging with the Wide Field Camera 3 (WFC3). The full HST dataset over the HUDF comprises imaging in eight bands: F435W, F606W, F775W and F850LP with ACS, and F105W, F125W, F140W and F160W with WFC3 (hereafter referred to as B$_{435}$, V$_{606}$, I$_{775}$, Z$_{850}$, Y$_{105}$, J$_{125}$, H$_{140}$ and H$_{160}$, respectively), which cover an area of $\sim 5 \text{ arcmin}^2$. The HUDF09 survey also obtained deep WFC3 imaging over two similarly-sized flanking fields, first observed with ACS in the UDF05 survey (PI Stiavelli; Oesch et al. 2007), referred to as the HUDF09-01 and HUDF09-02 fields (Bouwens et al. 2011b). These fields each have imaging in the V$_{606}$, I$_{775}$, Z$_{850}$, Y$_{105}$, J$_{125}$, and H$_{160}$ bands.

The majority of our galaxy sample comes from the Cosmic Assembly Near-infrared Deep Extragalactic Legacy Survey (CANDELS; Pfs Faber and Ferguson; Grogin et al. 2011; Koekemoer et al. 2011). CANDELS is the largest HST project ever, comprising 902 orbits over five extragalactic deep fields, including the two GOODS fields (Giavalisco et al. 2004), which finished in August 2013. CANDELS is composed of a deep and a wide survey. The deep survey covers the central $\sim 50\%$ of each of the two GOODS fields, while the wide survey covers the remainder of the GOODS-N field, and the southern $\sim 25\%$ of the GOODS-S field to depths $\sim 1 \text{ mag}$ shallower than the deep survey (the wide survey also covers three additional fields not used in this study; see §6.4.1 and Figure 15). We use ACS imaging from the original GOODS survey in the B$_{435}$, V$_{606}$, i$_{775}$ and z$_{850}$ bands. We use the most recent ACS mosaics in these fields, which is version 3 in the GOODS-S field, which includes all ACS imaging in that field prior to the ACS repair on Serving Mission 4 in 2009, and version 2 in the GOODS-N field, which includes all ACS imaging from the GOODS survey. The CANDELS imaging in both the deep and wide regions of both GOODS fields includes the Y$_{105}$, J$_{125}$ and H$_{160}$ bands. We add to our GOODS-S dataset imaging over the northern $\sim 25\%$ of the GOODS-S field from the WFC3 Science Oversight Committee’s Early Release Science (ERS) program (PI O’Connell; Windhorst et al. 2011), which also includes J$_{125}$ and H$_{160}$ imaging, as well as the F098M (hereafter referred to as Y$_{098}$) band. Unless otherwise distinguished, throughout the paper we will refer to Y$_{098}$ and Y$_{105}$ together as the Y-band (both filters probe observed 1$\mu$m light, but the Y$_{098}$ filter is $\sim$half of the width of Y$_{105}$, for somewhat higher spectral resolution).

Finally, we complete our dataset with the recently obtained HST observations near the galaxy clusters Abell 2744 and MACS J0416.1-2403 (hereafter MACS0416) from the Hubble Frontier Fields (HFF) program (PI Lotz). For this study, we use only the parallel (unlensed) fields. Both fields have been observed in the B$_{435}$, V$_{606}$, I$_{125}$, Y$_{105}$, J$_{125}$, H$_{140}$ and H$_{160}$ bands. We use these data to complement our galaxy samples at $z = 5, 6, 7$ and 8.

In parallel to the primary WFC3 observations, CANDELS obtained extremely deep imaging in the F814W band (hereafter F$_{814}$) in both of the GOODS fields. As these data were obtained recently, they suffer from poor charge transfer efficiency. Although algorithms have been devised to correct for this (Anderson & Bedin 2010), as the CANDELS fields have imaging in both the I$_{775}$ and z$_{850}$ bands, we do not include the CANDELS F$_{814}$ photometry in the initial photometric redshift fitting (though we do explore its inclusion in §3.6). However, we did use these very deep data during our visual inspection step, which was highly useful at $z = 8$, where true $z = 8$ galaxies should be completely undetected in the I$_{628}$-band. In the HFF parallel fields, where the I$_{125}$ band is the only imaging covering the red end of the optical, we used these data in the full analysis.

The description of the CANDELS HST imaging reduction is available from Koekemoer et al. (2011). These reduction steps were also followed for the ERS, HUDEF (Koekemoer et al. 2013) and HFF data we use here. We use imaging mosaics with 0.06" pixels, and make use of their associated weight and rms maps. The combined imaging dataset covers an area of 301.2 arcmin$^2$, with 5σ limiting magnitudes in the H$_{160}$ band ranging from 27.4 to 29.7 mag (measured in 0.4" apertures). These datasets are summarized in Table 1.

2.2. Point Spread Function Matching

The HST imaging used here spans more than a factor of three in wavelength, thus the differences in point-spread function (PSF) full-width at half-maximum (FWHM) across that range are significant. For example, the PSF in the GOODS-S Deep field has a FWHM = 0.193" in the H$_{160}$-band, but only 0.119" in the B$_{435}$-band. A point-source will thus have more of its flux contained within a 0.4" aperture in the B$_{435}$-band compared to the H$_{160}$-band. As the selection of distant galaxies relies very heavily on accurate colors, and we are using apertures of fixed sizes (determined by the detection image, see §2.3) to measure photometry in all bands, this changing PSF needs to be addressed.

We corrected for this by matching the PSF of the HST
imaging to the $H_{160}$-band image (which has the largest PSF FWHM) in each field. We did this using the IDL `deconv_tool` Lucy-Richardson deconvolution routine, in the same way as Finkelstein et al. (2010, 2012b). This routine requires the PSF for a given band as well as a reference PSF (in this case, the $H_{160}$-band), and it generates a kernel. The PSFs were generated by stacking stars in each field in each band, where the stars were selected via identifying the stellar locus in a half-light radius versus magnitude plane. Each star was then visually inspected to ensure that there were no bright neighbors, and then the stars were stacked, subsampling by a factor of 10 to ensure an accurate centroiding of each star (i.e., to avoid smearing the PSF during the stacking). Using these PSFs, the deconvolution routine performed an iterative process, and relies on the user to determine the number of iterations. We did this by making as close as the correct number of times, and then changing this number until the stars in the PSF-matched images in a given band had curves-of-growth which matched the $H_{160}$-band curves-of-growth to within 1% at a radius of 0.4″. The images were then convolved with the final kernel to generate PSF-matched images.

2.3. Photometry

Photometry was measured on the PSF-matched dataset with a modified version of the Source Extractor software (v2.8.6, Bertin & Arnouts 1996). Our modified version adds a buffer between the source and the local background cell and removes spurious sources associated with the distant wings of bright objects. Catalogs were generated independently in each of our ten sub-fields, using Source Extractor in two-image mode, where the same detection image was used to measure photometry from all available HST filters. For most of our fields, we used a weighted sum of the F125W and F160W images as the detection image, to increase our sensitivity to faint objects. In the HUDF main field and the MACS0416 and A2744 HFF parallel fields, we supplemented this catalog with catalogs using 10 additional detection images, derived by stacking all possible combinations of adjacent WFC3 filters. In these three fields, a combined catalog was made up of all unique sources in the catalogs, using a 0.2″ matching radius. This allowed very blue sources that may be too faint in the $H_{160}$ image to be selected in the original F125W+F160W-selected catalog to be included. This procedure was replicated in our completeness simulations (§4). To derive accurate flux uncertainties, Source Extractor relies on both an accurate rms map, and a realistic estimate of the effective gain. The provided rms map has been shown to produce accurate uncertainties, and it has been corrected for pixel-to-pixel correlations which occur as a result of the drizzling process (see Guo et al. 2013). The effective gains were computed for each band separately as the 1 (2.5) × the total exposure time for the ACS (WFC3) imaging. We have previously verified that the uncertainties measured in this manner on HST imaging are accurate (Finkelstein et al. 2012b). The zero-points to convert the observed fluxes into AB magnitudes are given in Table 1, and are appropriate for the dates when these data were taken.

Following our previous work (Finkelstein et al. 2010, 2012b, 2013), colors were measured in small Kron apertures with the Source Extractor Kron aperture parameter `PHOT_AUTOPARAMS` set to values of 1.2 and 1.7. Finkelstein et al. (2012b) found that these apertures result in more reliable colors for faint galaxies when compared to isophotal or small circular apertures. An aperture correction to the total flux was derived in the $H$-band and was computed as the ratio between this small Kron aperture flux, and the default Source Extractor `MAG_AUTO` flux, which is computed with `PHOT_AUTOPARAMS` = 2.5, 3.5. These aperture corrections were then applied to the fluxes in all filters. To see if our aperture corrections accurately recovered the total flux, we examined our completeness simulations (discussed in §4), and found that after applying this aperture correction recovered fluxes were typically 5% fainter in each band than their input fluxes. We thus increased the flux in each band by 5% to derive our best estimate of the total flux (with the exception of the HUDF main field, where the measured correction was 2%).

The Source Extractor catalogs from each band were combined into a master catalog for each field. At this step, the observed fluxes were corrected for Galactic extinction using the color excess E(B-V) from Schlafly & Finkbeiner (2011), appropriate for a given field1, and using the Cardelli et al. (1989) Milky Way reddening curve to derive the corrections based on each filter’s central wavelength. We used a mask image to remove objects in regions of bad data, where the mask was generated using a threshold value from the weight map. This mask primarily trims off the noisier edges of the imaging, but it also excludes the “death star” region on the WFC3 array when the number of dithers was low (i.e., in the CANDELS

---

recent evidence points to strong rest-frame optical emission. Now include an increased contribution from emission lines, as synthesis models (Fioc & Rocca-Volmerange 1997), which inspection (see §2.1). We used an updated set of templates pro-
in the CANDELS fields, which was used solely for visual in-
HST (Brammer et al. 2008). The input catalog used all available
for each fields were measured using the EAZY software
e.g., McLure et al. 2013; Schenker et al. 2013). Another advantage of photometric redshifts is that one obtains a redshift probability distribution function (PDF), which not only allows one to have a better estimate of the redshift uncertainty ($\sigma_z$ typically $\sim$0.2–0.3 versus 0.5 for the LBG technique), but can also be used as a tool in the construction of the sample itself. That being said, initial work comparing the differences between galaxy samples selected via both LBG and photometric redshift techniques found that the resulting sample properties are fairly similar (e.g., McLure et al. 2013; Schenker et al. 2013).

Photometric redshifts for all sources in the catalogs for each fields were measured using the EAZY software (Brammer et al. 2008). The input catalog used all available HST photometry, with the exception of the F814W imaging in the CANDELS fields, which was used solely for visual inspection (see §2.1). We used an updated set of templates provided with EAZY based on the PÉGASE stellar population synthesis models (Fioc & Rocca-Volmerange 1997), which now include an increased contribution from emission lines, as recent evidence points to strong rest-frame optical emission lines being ubiquitous amongst star-forming galaxy populations at high-redshift (e.g., Atek et al. 2013; Finkelstein et al. 2012b, 2013; van der Wel et al. 2011; Smit et al. 2014; Stark et al. 2013, Finkelstein et al. 2013). We also include an additional template based on the rest-frame UV spectrum of the young, unreddened galaxy Q2343-BX418 (Erb et al. 2010), as it retains characteristics expected in high-redshift galaxies, such as strong Lyα emission. EAZY assumes the intergalactic medium (IGM) prescription of Madau (1995). EAZY does have the option to include magnitude priors when fitting photometric redshifts, which uses the luminosity functions as a prior for whether a galaxy at a given apparent magnitude resides at a given redshift. As we show later, there is still non-negligible uncertainty at the bright end of the luminosity function, therefore we did not include these magnitude priors during our photometric-redshift fitting process.

### 3. Sample Selection

#### 3.1. Photometric Redshifts

We selected our high-redshift galaxy sample via a photometric redshift fitting technique. This has the advantage in that it uses all of the available photometry simultaneously, rather than the multi-step Lyman break galaxy (LBG) method, which selects galaxies using two colors, and then may impose a set of optical non-detection criteria (e.g., Bouwens et al. 2007, 2011b). Another advantage of photometric redshifts is that one obtains a redshift probability distribution function (PDF), which not only allows one to have a better estimate of the redshift uncertainty ($\sigma_z$ typically $\sim$0.2–0.3 versus 0.5 for the LBG technique), but can also be used as a tool in the construction of the sample itself. That being said, initial work comparing the differences between galaxy samples selected via both LBG and photometric redshift techniques found that the resulting sample properties are fairly similar (e.g., McLure et al. 2013; Schenker et al. 2013).

Photometric redshifts for all sources in the catalogs for each fields were measured using the EAZY software (Brammer et al. 2008). The input catalog used all available HST photometry, with the exception of the F814W imaging in the CANDELS fields, which was used solely for visual inspection (see §2.1). We used an updated set of templates provided with EAZY based on the PÉGASE stellar population synthesis models (Fioc & Rocca-Volmerange 1997), which now include an increased contribution from emission lines, as recent evidence points to strong rest-frame optical emission lines being ubiquitous amongst star-forming galaxy populations at high-redshift (e.g., Atek et al. 2013; Finkelstein et al. 2012b, 2013; van der Wel et al. 2011; Smit et al. 2014; Stark et al. 2013, Finkelstein et al. 2013). We also include an additional template based on the rest-frame UV spectrum of the young, unreddened galaxy Q2343-BX418 (Erb et al. 2010), as it retains characteristics expected in high-redshift galaxies, such as strong Lyα emission. EAZY assumes the intergalactic medium (IGM) prescription of Madau (1995). EAZY does have the option to include magnitude priors when fitting photometric redshifts, which uses the luminosity functions as a prior for whether a galaxy at a given apparent magnitude resides at a given redshift. As we show later, there is still non-negligible uncertainty at the bright end of the luminosity function, therefore we did not include these magnitude priors during our photometric-redshift fitting process.

#### 3.2. Selection Criteria

We selected galaxy samples in five redshift bins centered at $z = 4$, 5, 6, 7 and 8 with $\Delta z = 1$, using criteria similar to our previous work (Finkelstein et al. 2012b, 2013). The cosmic time elapsed between our last two bins at $z \approx 7$ and $z \approx 8$ is $\sim 125$ Myr. This time is much longer than the dynamical time of the systems we study, and thus leaves significant time for evolution. However, as studies of galaxy evolution move towards higher redshift, this will not always be the case (e.g., $\Delta t = 13–12 = 40$ Myr) thus future studies with the James Webb Space Telescope will need to pay careful attention to the choice of sample redshifts when studying galaxy evolution.

Rather than relying solely on the best-fit redshift value, we used the full redshift probability distribution curves $P(z)$ calculated by EAZY (where $P(z) \propto \exp(-\chi^2)$, normalized to unity). Our selection criteria are:

1) $A \geq 3.5$ significance detection in both the $J_{125}$ and $H_{160}$ bands. A requirement of a significant detection in two bands removes nearly all spurious sources, as the chances of a noise peak occurring in two images at the same position are very small ($\sigma_1\sigma_2 = \sigma_{\min}$). This requirement also limits our analysis to galaxies with $z < 8.5$, as the

![Figure 1: The absolute magnitude distribution of all galaxies in our redshift samples. The shaded color denotes which of the sub-fields a given galaxy was detected in. This figure demonstrates that while the HUDF is useful for finding the faintest galaxies, the CANDELS imaging is necessary to discover much larger numbers, as well as to probe a large dynamic range in luminosity.](image-url)
Lyman-break shifts into the $J_{125}$ band at $z = 8.1$.

2) The integral under the primary redshift peak must comprise at least 70% of the total integral of the redshift probability distribution function. This enforces that no more than 30% of the integrated redshift PDF can be in a secondary redshift solution.

3) The integral under the redshift PDF in the redshift corresponding to a given sample (i.e., $6.5 - 7.5$ for the $z = 7$ sample) must be at least 25%, which ensures that the redshift PDF is not too broad.

4) The area under the curve in the redshift range of interest must be higher than the area in any other redshift range (i.e., for a galaxy in the $z = 7$ sample, the integral of $P(6.5 < z < 7.5)$ must be higher than the integral in any other redshift bin). This criterion ensures that a given galaxy cannot be included in more than one redshift sample.

5) At least 50% of the redshift PDF must be above $z_{\text{sample}} - 1$ (i.e., $P(z > 6) > 0.5$ for $P_{\text{sample}} = 7$), and the best fit redshift must be above $z_{\text{sample}} - 2$.

6) The $\chi^2$ from the fit must be less than or equal to 60. This criterion ensures that EAZY provides a reasonable fit, though in practice it does not reject many sources.

7) Magnitude in the $H_{160}$ band must be $\geq 22$. This effectively cleans many stars from our sample, but the limit is bright enough such that it is still more than two magnitudes brighter than our brightest $z \geq 6$ galaxy candidate. At $z = 4$, we do have a few sources close to this limit, but only two sources are brighter than $H = 22.4$. This fact, coupled with the observation that the very few sources at $H < 22$ that satisfy our $z = 4$ selection criteria are either obvious stars, or diffraction spikes, implies that this criterion should not significantly affect our luminosity function results.

Of these criteria, items #1 and #2 are by far the most constraining, as most galaxies which meet these criteria, with $z_{\text{best}} > 3.5$ make it into our sample. Items #3 and #4 are responsible for putting a galaxy in a given redshift sample. While some of the cuts above are arbitrary, these choices will be corrected for as we apply these same criteria to our completeness simulations discussed in §4. In Figure 2, we compare the photometric redshifts for 171 galaxies in our sample to available spectroscopic redshifts in the literature. The agreement is excellent, with $\sigma_P(z_\text{spec} | z_{\text{sample}}) = 0.031$ (derived by taking an iterative 3$\sigma$-clipped standard deviation), though the number of confirmed redshifts at $z > 6.5$ is small (only five galaxies). The number of outliers is also small, with only six out of 171 galaxies (3.5%) having a photometric redshift differing from the spectroscopic redshift by $\Delta z > 1$ at $\geq 3\sigma$ significance. All of these six galaxies have $z_{\text{spec}} \geq 4$, thus no galaxies in our sample have a catastrophically lower spectroscopic redshift. In comparison, defining outliers in the same way, we find that the published CANDELS team photometric-redshift catalog has 13 outliers out of 174 total spectroscopic redshifts, plus a somewhat higher outlier fraction of 7.5% (Dahlen et al. 2013). Although the fraction of galaxies with confirmed redshifts is relatively small, the available spectroscopy confirms that our selection methods yield an accurate high-redshift sample.

3.3. Visual Inspection

As the candidate selection process is automated, for a truly robust galaxy sample, we required a visual inspection each of our ∼7500 candidate high-redshift galaxies. During the visual inspection, we examined the following features:

- Is the aperture drawn correctly? While the small Kron apertures yield the most reliable colors, they are also susceptible to “stretching” (i.e., becoming highly elongated) in regions of high noise or near very bright objects. For each source, we compared the ratio of the flux between the Kron aperture and a 0.4"-diameter circular aperture to that same quantity for objects of a similar magnitude from the full photometry catalog. If an object had a value $\geq 30\%$ higher than similarly bright sources in the full photometry catalog and the aperture looks to have been affected by noise/bright sources, we adjusted the photometry of the object in question accordingly, using the 0.4"-to-total correction of similarly-bright objects in the catalog. In practice, these issues affected <10% of galaxies in our high-redshift sample.

- Is there significant optical flux that did not get measured correctly? Primarily due to the issues with inaccurate apertures discussed in the above bullet, a very small number of sources appeared to have optical flux when visually inspected that was not measured to be significant in our catalog (i.e., in the case of a too-large aperture, the flux is concentrated in a small number of pixels, while the flux error comes from the full aperture, so the signal-to-noise is low). In these cases, objects were removed from our sample. This step is somewhat qualitative, as there are cases of objects where the aperture appears correct, yet there is still a $\sim 1-2\sigma$ detection in a single optical band. In the majority of these cases, as we are confident in our photometric redshift analysis, we left these objects in the sample. During this step, we also examined $I_{814}$ photometry for each source in the CANDELS fields, which primarily benefits the selection of $z = 8$ galaxies, which should not be visible at this wavelength. Three $z = 8$ candidates with observable $I_{814}$ flux were removed from our sample.

3.4. Stellar Contamination

The most crucial step in our visual inspection is the classification and removal of stellar sources, as stellar contamination would dominate the bright-end of the luminosity function if these contaminants were not considered. In particular, M-type stars as well as L and T brown dwarf stars can have similar colors (including optical non-detections) as our high-redshift galaxies of interest, particularly at $z \geq 6$. While some studies use dwarf star colors during their selection (e.g., Bowler et al. 2012, McLure et al. 2013, Bowler et al. 2014),
many use primarily the Source Extractor “stellarity” parameter to diagnose whether a compact object is a star or a galaxy (e.g., Bouwens et al. 2011b, 2014). However, the stellarity parameter loses its ability to discern between a point source and a resolved source for faint objects. To test this further, we examined the stellarity of sources in the CANDELS GOODS catalogs. At very bright magnitudes ($J_{125} < 24$), there is a clear separation between stars and galaxies, with objects either having a stellarity near unity (i.e., stars), or having stellarity near zero (i.e., galaxies). However, this separation becomes less clear at $J_{125} > 25$, where the stellar and galaxy sequences begin to blend together. Therefore, stellarity can be an unreliable star-galaxy separator at $J_{125} > 25$, which is similar to the brightness of our brightest $z \geq 7$ galaxies.

While the GOODS fields cover relatively small regions on the sky, the potential number of brown dwarf contaminants, even at $J_{125} > 25$, is significant. The Galactic structure model of Ryan & Reid (in prep) predicts the surface density of brown dwarfs in our covered fields. In the GOODS-S region, using the area covered by the CANDELS, ERS and HUDF09 observations, we would expect ~6 stars of spectral type M6–T9 with $J_{125}$-band magnitudes between 25 and 27. The surface density of M6-T9 stars in GOODS-N is similar, with an expected number of stars in the field of ~5. Thus, the expected number of $25 < J_{125} < 27$ stars of spectral type M6-T9 in our whole surveyed region is ~11. While this number is small, the numbers of brown dwarfs are expected to fall off toward fainter magnitudes, thus the majority of these are likely have $J_{125}$ close to 25. This magnitude is similar to those of the brightest galaxies in our sample, which dominate the shape of the bright end of the galaxy luminosity function. As stellarity is an unreliable method of identifying these sources, we must find an alternative method.

Although brown dwarfs can have similar colors to $z > 6$
galaxies, and can be included in the initial sample, they fall on well-defined color sequences, and can thus be distinguished from true galaxies. Figure 3 shows two color-color plots\(^3\) which we used in tandem with the size information, examining not only starlikeness, but also the FWHM and half-light radius as measured by Source Extractor, to identify stars lurking in our sample (similar plots were used at \(z = 4\) and 5). If a galaxy appeared un-resolved (defined as having a stellarity > 0.8, or a half-light radius and/or FWHM similar to that of stars in the field) then we examined that object in the color-color plots as shown in Figure 3. If the object also had colors similar to a dwarf star, then we removed it from our sample. Over all of our fields, we had a total of 23 objects flagged as stars in our \(z \geq 6\) samples; 18 from our initial \(z \sim 6\) galaxy sample, and 5 from our initial \(z \sim 7\) galaxy sample. These objects were removed from our sample. One of these stars removed from our \(z \sim 7\) sample was previously flagged as a probable T-dwarf by Castellano et al. (2010). We examined the subset of eight of these stars which were detected in the FourStar Galaxy Evolution (zFourGE) medium band imaging survey of a portion of GOODS-S, and found that all eight have \(J - J1 > 1\) and \(J1 - J3\) colors consistent with brown dwarf stars (Tilvi et al. 2013). Of these, six stars have \(J1 < 25\), meaning that our high-redshift galaxy selection criteria also originally selected \(\sim 1/2\) of the expected number of faint brown dwarfs in this field. Four of these six stars have Source Extractor stellarity measurements < 0.8, thus a stellarity-only rejection method would have failed to remove them. We conclude that our visual inspection step efficiently removed stellar contaminants from our sample, but we emphasize that the color examination portion was crucial to exclude the faintest stars from our sample.

3.5. Active Galactic Nuclei

We screened for the presence of bright active galactic nuclei (AGN) in our sample by searching for counterparts in Chandra X-ray Observatory point source catalogs. In the GOODS-S field, we used the 4 Msec Chandra Deep Field – South (CDF-S) catalog of Xue et al. (2011), and in GOODS-N, we used the 2Msec Chandra Deep Field – North catalog of Alexander et al. (2003). These catalogs have average positional accuracies of 0.42" and 0.3", respectively. To be conservative, we searched for matches in each catalog out to a radius of 1". We then visually inspected each of the 34 galaxies in our sample with a match. Seven objects, all with Chandra catalog separations > 0.6", had nearby counterparts with positions consistent with the Chandra catalog, and thus are likely providing the X-ray emission; none of these sources had spectroscopic redshifts in the CDF-S catalog. The remaining 27 sources, all with separations < 0.6", had Chandra positions consistent with the X-ray emission coming from the galaxies in our sample. Secure spectroscopic redshifts were available for four of these 27 galaxies in the CDF-S catalog, of \(z = 3.06, 3.66, 3.70\) and 4.76. These 27 galaxies (25 from our \(z = 4\) sample, and two from our \(z = 5\) sample) were removed from our galaxy sample. This removal is conservative, as although the X-ray detections imply the presence of an AGN, it does not prove that the AGN dominates the UV luminosity.

3.6. Photometric Redshifts with Spitzer/IRAC Photometry

As we will discuss below, one of the main results of this work is an apparent constant value of \(M_{UV}\) at \(z > 5\), brighter than many previous works. It is thus imperative that we have high confidence that our bright galaxies are all in fact at high-redshift, and not lower-redshift contaminants. To provide a further check on our bright sources, we re-examined the photometric redshifts of our bright galaxies with the addition of Spitzer Space Telescope Infrared Array Camera (IRAC; Fazio et al. 2004) imaging over our fields. This imaging probes the rest-frame optical at these wavelengths, and thus provides significant constraining power because the most likely contaminants are red, lower-redshift galaxies, which would have very different fluxes in the mid-infrared than true high-redshift galaxies. We examined sources with \(M_{1500} < -21\), which is approximately the value of \(M_{1500}\) at these redshifts, and provides samples of 164, 85, 29, 18 and 3 bright galaxies at \(z = 4, 5, 6, 7\) and 8, respectively.

During the cryogenic mission, the GOODS fields were observed by the GOODS team (Dickinson et al., in prep) at 3.6, 4.5, 5.8, and 8.0 µm. Later, during Cycle 6 of the warm mission, broader regions encompassing the GOODS footprints were covered by the Spitzer Extended Deep Survey (SEDs; Ashby et al. 2013) to \(\sim 3\)σ depths of 26 AB mag at both 3.6 and 4.5 µm. A somewhat narrower subset of both fields was subsequently covered by Spitzer-CANDELS (S-CANDELS; M. Ashby et al., in preparation), to even fainter levels; reaching \(\sim 0.5\) mag deeper than SEDS in both of the warm IRAC bandpasses. The HUDF09 fields were observed by Spitzer programs 70145 (the IRAC Ultra-Deep Field, Labbé et al. 2013), reaching 120, 50 and 100 hr in the HUDF Main, PAR1 and PAR2 fields, respectively. Finally, program 70204 (PI Fazio) observed a region in the ERS field to 100 hr depth. The current work is based on mosaics constructed by coadding all the above data following the procedures described by Ashby et al. (2013). The combined data have a depth of \(\geq 50\) hr over both CANDELS GOODS fields and \(> 100\) hr over the HUDF main field.

As the IRAC PSF is much broader than that of HST, our galaxies may be blended with other nearby sources. We measured Spitzer/IRAC 3.6 and 4.5 µm photometry by performing PSF-matched photometry on the combined IRAC data, which reach at least 26.8 AB mag (5σ) at 3.6 and 4.5 µm (Ashby et al. in prep.). We utilized the TPHot software (Merlin et al., in prep.), an updated version of TPFIT (Laidler et al. 2007), to model low-resolution images (IRAC images) by convolving the H-band image with empirically derived IRAC PSFs and simultaneously fitting all IRAC sources. Specifically, we used the light profiles and isophotes in the detection (\(J + H\)) image obtained by Source Extractor, and then convolved them to the high resolution image with a transfer kernel to generate model images for the low-resolution data. These models were then fit to the real low-resolution images, dilating the segmentation maps of the model images to account for missing flux on the edges of galaxies (Galametz et al. 2013). The fluxes of sources are determined by the model which best-represents the real data. As the PSF FWHM of the high-resolution image (H-band) is negligible (\(< 0.19\)") compared to those of the low-resolution IRAC images (\(< 1.7\)"), we use the IRAC PSFs as transfer kernels. We derive empirical PSFs by stacking isolated and moderately bright stars in each field. As our own WFC3 catalog was used as the input for TPHot, all of our galaxies have measurements in the TPHot catalogs. We visually inspected the positions of each of our high-redshift galaxy candidates in the IRAC images to ensure no significant

---

\(^3\) This research has benefitted from the Spox Prism Spectral Libraries, maintained by Adam Burgasser at http://pono.ucsd.edu/~adam/browndwarfs/spxprism
contamination from the residuals of nearby bright galaxies. If an object was on or near a strong residual, we ignored the IRAC photometry in the subsequent analysis. This was the case for 18/164 galaxies at $z = 4$, 23/85 at $z = 5$, 3/29 at $z = 6$, 6/18 at $z = 7$ and 1/3 at $z = 8$. With these contaminated fluxes removed, we found that all remaining $M_{1500} < -21$ galaxies at $z = 4–8$ had 3.6 μm detections of at least 3σ significance, with a magnitude range at $z \geq 6$ of $22.7 \leq \mu_{3.6} \leq 25.8$. The full description of our TPHOT IRAC photometry catalog will be presented in M. Song et al. (in prep).

We reran EAZY for this subsample of bright galaxies, including the Spitzer/IRAC fluxes, as well as photometry from the ACS F814W filter, which was not included in the original photometric redshift calculation (see §2.1). We examined these updated photometric redshift results, searching for galaxies in our $z = 4$ and 5 samples with $z_{\text{new}} < 2.5$, and in our $z = 6, 7$ and 8 samples with $z_{\text{new}} < 4$. We found 14 out of 164 galaxies in our $z = 4$ sample and 14 out of 85 galaxies in our $z = 5$ sample with $z_{\text{new}} < 2.5$. We found one galaxy out of 29 at $z = 6$ that appears to better fit with a low-redshift solution, of $z_{\text{new}} = 0.9$, while zero galaxies in our $z = 7$ or 8 samples had preferred low-redshift solutions with the inclusion of IRAC photometry.

We examined each of the 29 $z = 4–6$ galaxies that had preferred low-redshift solutions with the inclusion of the IRAC photometry to examine whether the updated redshift yielded a spectral energy distribution consistent with the observed photometry. Out of the 28 $z = 4$ or 5 galaxies with preferred low-redshift solutions, 23 had photometry consistent with a true low-redshift galaxy. Four galaxies, however, had photometry which appeared to be consistent with a high redshift galaxy with a strong emission line (Hα or [O III]) in one IRAC band. Systems with lines such as these (i.e., EW[H[II] ] > 500 Å) are rare locally, but appear to be more common at high-redshift (e.g., van der Wel et al. 2011; Finkelstein et al. 2013; Smit et al. 2014). Although typical emission lines strengths are now included in the EAZY templates, these do not account for extreme emission lines, thus it is not surprising that EAZY does not return a high-redshift solution. We elect to keep these four galaxies in our sample, noting that the lack of strong

![Figure 4](image-url)

**Figure 4.** The SED of the only galaxy in our 50-object sample of bright ($M_{1500} < -21$) $z \geq 6$ galaxies which had a photometric redshift which preferred a low-redshift solution after the inclusion of IRAC and F814W photometry. The blue curve shows the original high-redshift best-fitting stellar population model and photometric redshift probability distribution function, while the red curve shows the results including IRAC and F814W. This galaxy was removed from our sample, as the IRAC photometry is consistent with the stellar emission peak at $z \sim 1$. The inferred contamination rate of 2% (one out of 50 galaxies) is even lower than our estimates for $z \geq 6$ in §3.8.

the updated (2007) stellar population synthesis models of Bruzual & Charlot (2003) to generate a grid of spectra, varying the stellar population metallicity, age, and star-formation history. Metallicities spanned $0.02 - 1 \times$ Solar, and ages spanned 1 Myr to the age of the universe at a given redshift. We allowed several different types of star-formation histories (SFHs), including a single burst, continuous, as well as both exponentially decaying and rising (so-called “tau” and “inverted-tau”) models. To these spectra, we added dust attenuation using the starburst attenuation law of Inoue (2011), based on the number of ionizing photons from a given model, and assuming the photon escape fraction is $\approx$ zero. We then redshifted these models to $0 < z < 11$ and added intergalactic medium (IGM) attenuation (Madau 1995). These model spectra were integrated through our HST filter bandpasses to derive synthetic photometry for comparison with our observations. For each model, we computed the value of $M_{1500}$ by fitting a 100 Å-wide synthetic top-hat filter to the spectrum centered at rest-frame 1500 Å. Likewise, for each model we measured the value of $\beta$ by fitting a power law to each model spectrum using the wavelength windows specified by Calzetti et al. (1994), similar to Finkelstein et al. (2012b).

The best-fit model was found via $\chi^2$ minimization, including an extra systematic error term of 5% of the object flux for each band to account for such items as residual uncertainties in the zeropoint correction and PSF-matching process. The stellar mass was computed as the normalization between the best-fit model (which was normalized to 1 $M_\odot$) and the observed fluxes, weighted by the signal-to-noise in each band. These best-fit values of $M_{1500}$ are used in our luminosity function analysis below, while $\beta$ is used to correct for incompleteness in a color-dependent fashion. The uncertainties in the best-fit parameters were derived via Monte Carlo simulations, perturbing the observed flux of each object by a number drawn from a Gaussian distribution with a standard deviation equal to the flux uncertainty in a given filter. For each galaxy, 10$^3$ Monte Carlo simulations were run, providing a distribution of 10 values for each physical parameter. The 68% confidence range for each parameter was calculated as the range of the central 68% of results from these simulations. In these simulations, the best-fit redshift was allowed to vary following the redshift probability distribution function, thus folding in the uncertainty in redshift into the uncertainty in the physical parameters (most notably, the stellar mass and $M_{1500}$). Finkelstein et al. (2012b). During this process, we only allowed the redshift to vary within $\Delta z < \pm 1$ of the best-fit photometric redshift. This excludes any low-redshift solution from biasing the uncertainties on a given parameter. The amount of the integrated $P(z)$ at $z > 3$ excluded via this step was typically $\lesssim 10\%$ (at $z = 6$).

### 3.8. Contamination

A key issue in any study of high redshift galaxies is the risk of sample contamination, either by spurious sources or by lower-redshift interlopers. The gold standard for eliminating contamination is to obtain spectroscopic redshifts. This is clearly unfeasible for all galaxies in our sample (until the next generation of space and ground-based telescopes), but there is significant archival spectroscopic data. As discussed in §3.2, we find excellent agreement between available spectroscopic redshifts and our photometric redshifts, with $\sigma_{\Delta z/(1+z)} = 0.031$. In particular, the four bright galaxies (24.9 $< J_{125} < 25.7$) with confirmed $z_{\text{spec}} > 6.5$ have quite excellent agreement.

Note: — A catalog of our 7446 galaxies, with their derived properties. We include the IAU designation in continuity for previous and future works, with a designation prefix HRG14 denoting “High Redshift Galaxy 2014”. The values in parentheses represent the 68% confidence range of the derived parameters. Here, we show 20 representative galaxies, four from each redshift bin. This table is available in its entirety in a machine-readable form in the online journal. A portion is shown here for guidance regarding its form and content.
tionally, the slightly updated photometry pushes the photometric redshift of CANDELS GOODS-N data, thus the catalog numbering is different. Additionally (Finkelstein et al. 2013). Our new catalog uses an updated version of the for a similar analysis). To avoid biasing from real objects ages in the GOODS-S Deep field (see Schmidt et al. (2014) for a typical LBG color-color selection sample (e.g., Bouwens et al. 2007), though the observed flux can be explained by non-ionizing photons transmitted through the Lyα forest.

In general, spectroscopic followup of sources selected on the basis of their Lyman breaks (either color-color selection, or photometric redshift selection) finds a very small contamination by low-redshift sources (e.g., Pentericci et al. 2011). However, given the apparent difficulty in detecting Lyα emission at z > 6.5 (e.g., Pentericci et al. 2011; Ono et al. 2012; Finkelstein et al. 2013), the true effect of contamination at these higher redshifts is not empirically known. In this subsection, we will attempt to estimate our contamination fraction by other means.

### 3.8.1. Properties of the Image Noise

Two key components of our selection processes should eliminate contamination by spurious sources in our sample. First, we restricted our sample to galaxies detected at z > 3.5σ in two imaging bands: $J_{125}$ and $H_{160}$. Formally, requiring a 3.5σ detection in a single band should yield only a 0.05% contamination by noise. However, the wings of the noise distribution are highly non-Gaussian. We examined this by measuring the fluxes at $2 \times 10^5$ random positions in the $J_{125}$ and $H_{160}$ images in the GOODS-S Deep field (see Schmidt et al. (2014) for a similar analysis). To avoid biasing from real objects in the image, we only considered negative fluctuations (e.g.,

### 3.8.2. Estimates from Stacked Redshift PDFs

Contamination by low-redshift interlopers is a more complicated issue. While extreme emission line galaxies at lower-redshift could theoretically be an issue (Atk et al. 2011), our requirement of detections in two bands (as well as the frequent detections in more than two bands for all but the highest redshift objects in the z = 8 sample) makes a significant contamination by these sources unlikely. The most likely possible contaminants are faint red galaxies at z ≤ 2 (e.g., Dickinson et al. 2000). These galaxies can be too faint to be detected in our optical imaging, but their red SEDs yield detections in the WFC3/IR bands. Although faint sources that are very red will have a disfavored high-redshift solution with our current photometric selection, we have information on their likelihoods encoded in our redshift PDFs. Figure 5 shows the redshift PDFs of galaxies in each of our three highest redshift samples, stacked in magnitude bins of ∆M = 1 mag. At all redshifts and all magnitudes, ≥85% of the redshift PDF is at $z > 4$, implying that there is not significant contamination by lower-redshift galaxies. The position of the secondary redshift peak is consistent with the redshift where we detected spectral break due to a 4000 Å break rather than the Lyman break (at z = 6, 7 and 8, this gives $z_{\text{secondary}} = 1.1, 1.4$ and 1.7). At $z = 8$, the possible contamination is <10.5%, primarily due to the fact that at z = 8, a galaxy will have to be undetected in most of the filters we consider here. The worst

![Redshift PDFs for galaxies in each of our three redshift samples, stacked in bins ∆MUV = 1. The legends give the number of galaxies in each stack, as well as the fraction of the redshift PDF at z > 4 (denoted as P). Even in the worst case (which is for faint-galaxies at z = 6) <16.3% of the sample could possibly be at lower redshift.](image-url)
case is for faint galaxies at $z=6$, as $z=6$ galaxies are typically detected in all but two filters, though even here, the indicated contamination is $\lesssim 15\%$.

3.8.3. Stacking Imaging

The limits from the previous subsection are likely upper limits on the contamination fraction. When fitting photometric redshifts, to rule out all low-redshift solutions, the Lyman break needs to be detected at high significance, which is the case for only the brightest galaxies (e.g., at $z=6$, the brightest bin has a contamination of $<2\%$). Additionally, these results are dependent on the templates used, which by definition do not account for unknown galaxy populations. We therefore consider two empirical tests of contamination. The first is to stack all galaxies in a sample, in order to search for detections below the Lyman break. The results from this test for $z=6, 7$ and 8 are shown in Figure 6. As expected for galaxies at the expected redshifts, there is no visible signal in the $B_{335}$-band at $z=6$, $I_{777}$-band and blueward at $z=7$, and $I_{814}$-band and blueward at $z=8$. This confirms our previous conclusion that there is not a significant contamination by lower-redshift sources in our sample.

3.8.4. Estimates from Dimmed Real Sources

As a final test, we estimated the contamination by artificially dimming real lower redshift sources in our catalog, to see if the increased photometric scatter allows them to be selected as high redshift candidates. This empirical test is useful as it does not rely on known spectral templates to derive the contamination, though it does assume that the fainter objects which could potentially contaminate our sample have similar SEDs to the bright objects which we dim. We performed this exercise twice, once using the combined catalog of the GOODS-S and GOODS-N Deep fields, and once in the HUDF main field, to probe fainter magnitudes. In the GOODS Deep fields, we selected all real sources with $21 < H_{160} < 24$ and $z_{\text{phot}} < 3$, and reduced their observed fluxes by a factor of 20. The same was done for sources drawn from the HUDF Main field, here extending the magnitude range to be $21 < H_{160} < 26$. The limits on these magnitudes were chosen to exclude any real high-redshift sources. We replaced the true flux uncertainties of these objects with flux uncertainties from a randomly drawn real source from the full catalog from a given field with a similar magnitude as the dimmed source. We then added scatter to the dimmed fluxes, perturbing them by a random amount drawn from a Gaussian distribution with a standard deviation equal to the flux uncertainties of the object. We included two realizations of the HUDF field to increase the number of dimmed objects.

The total number of sources in our artificially dimmed catalog was 4066 in the Deep fields, and 1254 in the HUDF field. We measured photometric redshifts of these sources with EAZY in an identical manner as on our real catalogs, and then we applied our sample selection to this dimmed catalog. In the Deep fields, we found a total number of 149, 134, 54, 23 and 8 dimmed objects satisfied our $z=4, 5, 6, 7$ and 8 selection criteria. Investigating the original (not dimmed or perturbed) colors of these sources, we found that they are unsurprisingly red, with the bulk of sources having $V-H > 2$ mag. It is therefore this parent population of red sources which are responsible for the majority of the possible contamination. The contamination fraction in our high-redshift sample was then defined as

$$F = \frac{N_{\text{dimmed select}}}{N_{\text{total red}}} = \frac{N_{\text{dimmed red}}}{N_c}$$

where, $N_{\text{dimmed select}}$ was the number of dimmed sources satisfying our high-redshift sample selection, $N_{\text{dimmed req}}$ was the total number of sources in the dimmed catalog with original colors of $V-H < 2$, $N_{\text{total req}}$ was the number of sources in the full object catalog with $25 < H < 27$, $z_{\text{phot}} < 3$, and $V-H < 2$, and $N_r$ was the number of true galaxy candidates in a given redshift bin. For example, at $z=6$, where we found 54 dimmed galaxies satisfied our selection criteria ($N_{\text{dimmed select}} = 54$), $N_{\text{dimmed red}} = 1023$, $N_{\text{total red}} = 695$, and $N_c = 322$, giving an estimated contamination fraction $F$ = 11.4\%. Therefore, for sources with $25 < H < 27$, we found an estimated contamination fraction of $F = 4.5\%$, $8.1\%$, $11.4\%$, $11.1\%$ and $16.0\%$ at $z=4, 5, 6, 7$ and 8, respectively. We performed the same exercise in the HUDF, here for fainter sources with $26 < H < 29$, finding 30, 21, 8, 8 and 0 sources satisfied our $z=4, 5, 6, 7$ selection criteria, giving a contamination fraction of 9.1\%, 11.6\%, 6.2\%, 14.7\% and 4.9\% at $z=4, 5, 6, 7$ and 8.

Broadly speaking, we estimate relatively small contamination fractions of $\sim 5-15\%$, in-line with the estimates above from the stacked $P(z)$ curves. As the bulk of contaminants appear to be red galaxies, it is interesting to compare to the space density of these potentially contaminating sources. This was recently estimated by Casey et al. (2014b), who find that dusty star-forming galaxies at $z<5$ will contaminate $z>5$ galaxies samples at a rate of $<1\%$. This is much less than our contamination estimates, thus we may have overestimated the contamination rate, though it may not be inconsistent once photometric scatter is applied to faint, red galaxies, making it easier for them to scatter into our sample. In any case, the expected contamination rate is quite small, therefore we do not reduce our observed number densities for the expected minimal contamination.

4. COMPLETENESS SIMULATIONS

We performed an extensive set of simulations to estimate the effective volume for each source in our sample, accounting for both image incompleteness and selection effects. We inserted mock galaxies into the imaging data, repeating the same analysis for source detection, photometry, photometric redshift measurement, and sample selection as was done on the real data. We then compared the fraction of recovered and selected mock sources to the total number of input sources in a given bin of absolute magnitude and redshift to determine our completeness in that bin.

While the effective volumes are typically computed as a function of magnitude and redshift, other key factors in these simulations are the choices of galaxy size and color. At a constant magnitude, a very extended or very red galaxy may not make it into our sample, thus the effective volume depends not only on magnitude and redshift, but also on the size and rest-frame UV color. To see what effect this has, we have computed our completeness as a function of four properties: redshift, absolute magnitude, half-light radius, rest-UV color, where we have parametrized the latter via the UV spectral slope $\beta$. A large number of simulated objects are needed to fill out this four-dimensional space; our completed simulations recovered $\sim 5.4$ million out of 7 million objects input across all of our fields (where the recovered objects were detected in our photometry catalogs; this number
CANDELS: The Rest-Frame UV Luminosity Function at $z = 4–8$

**Fig. 6.** — Top: Filter transmission curves for the filter set used in this study ($V_{606}$, which was used in the GOODS-S ERS field only, is not shown). The vertical lines denote the relative position of the $\text{Ly}\alpha$ break (rest 1216 Å) in a given filter for galaxies at the center of our three highest redshift bins. Bottom) Image stacks of galaxies in our three highest redshift galaxy samples. If our sample had a significant fraction of lower-redshift interlopers, significant flux would be seen blueward of the break (e.g., $B_{435}$ at $z = 6$, $i_{775}$ and blueward at $z = 7$, and $I_{814}$ and blueward at $z = 8$). This is not observed at any redshift, thus we conclude that our sample is free of significant contamination.

**Fig. 7.** — The results of our completeness simulations, showing the probability that a given simulated source was recovered as a function of its input redshift. The solid lines denote sources with $M_{I_{814}} = -22$, while the dashed lines denote $M_{I_{814}} = -19$. These lines assume a half-light radius of $r_h = 0.18'$ and $\beta = -2.0$. The background histogram shows the distribution of best-fit photometric redshifts for the real galaxies in each redshift subsample. Although our selection criteria combined with the wavelengths probed by our filter-set results in a completeness that peaks at close to $z = 4, 5, 6, 7$ or 8, the evolving luminosity function as well as our sensitivity to bright galaxies results in our samples having mean redshifts slightly lower than the bin center, particularly in the higher redshift samples.

Our simulations were run separately on each of our 10 subfields defined in Table 1. To ensure that the mock galaxies did not affect the background estimation, a small number of galaxies were added during each simulation. To optimize the simulation runtime, the mock galaxies were added to cutouts from the full images. In the GOODS sub-fields (i.e., CANDELS Deep and Wide, and the ERS), 200 mock galaxies were added to a $2000 \times 2000$ pixel ($2' \times 2'$) region of the images, while for the single-pointing HUDF and HFF fields, 100 galaxies were added to a $1000 \times 1000$ pixel region. As the depth across our imaging data can vary, during each simulation the position of the cutout varied, such that when we combine all of our simulations, we average over any differences in the depth across a given field.

To determine the colors of the mock galaxies, we created distributions in redshift, dust attenuation (parameterized by $E(B-V)$), stellar population age and stellar metallicity. The redshift was defined to be flat across $3 < z < 9$, such that we simulate objects well above and below the redshift ranges of interest. The dust attenuation $E(B-V)$ was defined to have a

$\text{Ly}\alpha$ break (rest 1216 Å) in a given filter for galaxies at the center of our three highest redshift bins. Bottom) Image stacks of galaxies in our three highest redshift galaxy samples. If our sample had a significant fraction of lower-redshift interlopers, significant flux would be seen blueward of the break (e.g., $B_{435}$ at $z = 6$, $i_{775}$ and blueward at $z = 7$, and $I_{814}$ and blueward at $z = 8$). This is not observed at any redshift, thus we conclude that our sample is free of significant contamination.

**Fig. 7.** — The results of our completeness simulations, showing the probability that a given simulated source was recovered as a function of its input redshift. The solid lines denote sources with $M_{I_{814}} = -22$, while the dashed lines denote $M_{I_{814}} = -19$. These lines assume a half-light radius of $r_h = 0.18'$ and $\beta = -2.0$. The background histogram shows the distribution of best-fit photometric redshifts for the real galaxies in each redshift subsample. Although our selection criteria combined with the wavelengths probed by our filter-set results in a completeness that peaks at close to $z = 4, 5, 6, 7$ or 8, the evolving luminosity function as well as our sensitivity to bright galaxies results in our samples having mean redshifts slightly lower than the bin center, particularly in the higher redshift samples.

Our simulations were run separately on each of our 10 subfields defined in Table 1. To ensure that the mock galaxies did not affect the background estimation, a small number of galaxies were added during each simulation. To optimize the simulation runtime, the mock galaxies were added to cutouts from the full images. In the GOODS sub-fields (i.e., CANDELS Deep and Wide, and the ERS), 200 mock galaxies were added to a $2000 \times 2000$ pixel ($2' \times 2'$) region of the images, while for the single-pointing HUDF and HFF fields, 100 galaxies were added to a $1000 \times 1000$ pixel region. As the depth across our imaging data can vary, during each simulation the position of the cutout varied, such that when we combine all of our simulations, we average over any differences in the depth across a given field.

To determine the colors of the mock galaxies, we created distributions in redshift, dust attenuation (parameterized by $E(B-V)$), stellar population age and stellar metallicity. The redshift was defined to be flat across $3 < z < 9$, such that we simulate objects well above and below the redshift ranges of interest. The dust attenuation $E(B-V)$ was defined to have a
Gaussian distribution with a mean of 0.1 and a σ = 0.15 (with a minimum of zero). The age was defined as a log-normal distribution, with a peak near 10 Myr, and a tail extending out to the age of the universe at a given redshift. The metallicity distribution was also log-normal, with a peak of Z = 0.2Z⊙, and a tail towards higher values. The exact values of these distributions are not crucial given our methodology (as opposed to a multivariate analysis, where the distributions are very important), as they combine to create a distribution of rest-frame UV slope β. We crafted these distributions to provide a distribution of β encompassing the expected values for our real objects. We then used the updated (2007) stellar population models of Bruzual & Charlot (2003) to calculate the colors of a stellar population given the distributions above. To convert these colors into magnitudes, we assumed a distribution of H-band magnitudes designed to have many faint (H > 26) galaxies (which is where we expect to become incomplete), and relatively few at bright magnitudes. To ensure enough bright galaxies to calculate a robust incompleteness, every 10th simulation used a flat distribution of H-band magnitudes of 22 < H < 25. These H-band magnitudes were combined with the mock galaxy colors to generate magnitudes in each filter for a given field.

To generate the galaxy images themselves, we used the GALFIT software (Peng et al. 2002). We assumed a log-normal distribution of half-light radii with a peak at 1-pixel, and a high tail towards larger radii, giving an interquartile range of half-light radii of 1.4–4.9 pixels. This corresponds to ~0.4–1.6 kpc, spanning the range of the majority of resolved galaxies at z > 4 (e.g., Oesch et al. 2010a; Grazian et al. 2012; Ono et al. 2013; Curtis-Lake et al. 2014). GALFIT also requires a Sersic index (n), axis ratio and position angle; the Sersic index was assumed to be a log-normal distribution at 1 < n < 4, with the majority of the mock galaxies having disk-like morphologies (n < 2); the axial ratio was also log-normal, with a peak at 0.8, and a tail toward lower values, and the position angle was a uniformly distributed random value between 0 and 360 degrees. GALFIT was then used to generate a 101 × 101 pixel (6′ × 6′) stamp for a given mock galaxy, which was then added to the image at a random location. Because our data are PSF-matched to the H-band, we had GALFIT convolve the mock galaxy images with the H-band PSF prior to adding them to the data for all filters.

Once the set of mock galaxies for a given simulation were added to the data, photometric catalogs were generated using Source Extractor in the exact same manner as was done on the data. This requires making the same set of detection images, which we did here using weighted combinations of the simulated images. These catalogs were read in and combined, again in the same methodology as with the data, including aperture corrections (the exception here is that a correction for Galactic extinction was not applied in the simulation, as the simulated objects did not have Galactic extinction included). The photometric catalog was then compared with the input catalog to generate the list of recovered objects (i.e., mock galaxies which were recovered by Source Extractor); an object was regarded as being recovered if it had a positional match within 0.2′′ of one of the input mock galaxies. The recovered object catalogs were processed through EAZY to generate photometric redshifts, and then run through our SED-fitting routine to measure absolute UV magnitudes (MUV), stellar masses and UV spectral slopes. These simulations were then repeated until a large sample of recovered galaxies was available, which were then compiled in a single database per field. The completeness was defined as the number of galaxies recovered versus the number of input galaxies, as a function of input absolute magnitude, redshift, half-light radius and UV spectral slope β. Figure 4 shows the results from our simulations.

In our original simulations the recovered redshift was typically ~0.2 lower than the input redshift, independent of magnitude. This is likely not a fault in our photometric redshift estimates, as Figure 2 shows that these agree well with existing spectroscopic redshifts for real galaxies. Rather, it is likely a mismatch between our simulated SEDs and those of the templates used in EAZY. Upon further investigation, we found that the cause of this offset was Lyα emission in the mock galaxies. While Lyα photons were attenuated by dust in the same manner as adjacent UV photons, we did not include any additional Lyα attenuation for, e.g., geometric or kinematic effects. This led to very high Lyα escape fractions, which were not matched in the templates. This high Lyα emission reduced the amplitude of the Lyman break, resulting in a (slightly) lower photometric redshift. After reducing the amount of Lyα flux to 25% of the intrinsic value, our photometric redshifts matched the input redshifts. Rather than rerun all of our completeness simulations, we elected to simply reduce the input redshift by 0.2 when interpreting our simulations, which corrects for this effect (this changes the distance modulus by <0.1 mag). The exception was the simulations for the HFF parallel fields, which were run after this effect was noticed. In those fields, the input models had their Lyα flux reduced to 25% of the intrinsic value, and no change to the model redshift was needed.

It is important to examine whether the choice of computing the completeness as a function of input properties affects our result. As mentioned in §2.3, we used the results from these simulations to correct for offsets in the recovered versus input magnitudes (i.e., to be sure the fluxes we use represent the total flux). Additionally, we examined whether there exist biases in the half-light radius or β measurements from the simulations. Recovered objects were typically measured to have a half-light radius ~0.03′′ (0.5 pixels) smaller than the input value, and were measured to be slightly redder (Δβ ≲ 0.1). However, these corrections make effectively no change to the effective volumes derived from the simulations, and so were not applied.

In each redshift bin, the effective volume for galaxies in a given field was then calculated via

\[ V_{eff}(M_{1500}, r_h, \beta) = \frac{dV}{dz} P(M_{1500}, z, r_h, \beta) dz \]  

where \( dV/dz \) is the comoving volume element, and \( P(M_{1500}, z, r_h, \beta) \) is the result from our completeness simulations. The integral was done over \( \Delta z = 1 \), centered on the center of each redshift bin. In each field, we used a weighted mean of this three-dimensional effective volume \( V_{eff}(M_{1500}, r_h, \beta) \) to calculate \( V_{eff}(M_{1500}) \), where the weighting is based on the number of real objects in a magnitude bin with a given value of \( r_h \) and \( \beta \), as

\[ V_{eff}(M_{1500}) = \sum_{r_h} \sum_{\beta} V_{eff}(M_{1500}, r_h, \beta) N(M_{1500}, r_h, \beta) \]

This assumes that the completeness corrections estimated using our observed size and color distributions are similar to
what we obtained if we could measure the true sizes and colors, motivated by our measurement of minimal size and color biases when comparing the input to recovered values.

This weighted volume is the most representative of the true volume we are sensitive to, as we explicitly account for the incompleteness as a function of size and color. Figure 9 highlights the dependence of the effective volume on these quantities for galaxies in our $z = 6$ sample in the GOODS-N Deep field. The effective volume has a strong dependence on the surface brightness of galaxies, as the volume drops steeply both for larger sizes and fainter magnitudes. The central and right panels highlight that while the effective volume (and thus sample completeness) is sensitive to both size and color, the color has a relatively minor role. We remain sensitive to fairly red galaxies ($\beta = -1$), similar to previous results from Bouwens et al. (2012). We note that although the effective volume has a strong dependence on size, the relatively small sizes of galaxies in our sample yields a volume similar to that obtained when assuming a constant small size. Thus, although our volumes are the most accurate, had we assumed a fixed effective radius of, e.g., $r_e = 1$ kpc, our results would not change significantly. This is consistent with the conclusions of Grazian et al. (2012) who found, accounting for the size-luminosity relation when deriving the $z = 7$ luminosity function, similar results as previous studies that neglected the size-luminosity relation. Our final effective volumes are shown in Figure 8.

5. THE LUMINOSITY FUNCTION

5.1. Parametric Approach

Possessing our final galaxy sample with measured values of $M_{1500}$, as well as the effective volumes from our completeness simulations in the previous section, we can now proceed to measure the rest-frame UV luminosity function at $z = 4$, 5, 6, 7 and 8. We calculate the luminosity function in two ways: a parametric version assuming that the luminosity function takes the form of a Schechter (1976) function, and a non-parametric step-wise maximum likelihood (SWML) calculation.

The fitting of a Schechter function is well motivated, as it successfully matches the observed rest-UV luminosity functions at lower redshifts (e.g., Reddy & Steidel 2009, Bouwens et al. 2006). This function is characterized by a power-law at the faint-end with slope $\alpha$, and an exponential cut-off at the bright end, transitioning between the two regimes at the characteristic magnitude $M^*$. The parameter $\varphi^*$ sets the normalization of this function. The number den-
For the measurement of the luminosity function assuming a Schechter functional form, we calculated the likelihood that the number of observed galaxies in a given magnitude bin is equal to that for an assumed value of the Schechter parameters $M^*$ and $\alpha$. Rather than performing a grid-based search, we performed a Markov Chain Monte Carlo (MCMC) search algorithm, to better span the parameter space, as well as to better characterize the uncertainties on the Schechter parameters. We performed this calculation in bins of absolute magnitude with $\Delta M = 0.5$ mag, ranging from $-24 \leq M_{1500} \leq -17$. At the bright end we are in the limit of small numbers, therefore we model the probability distribution as a Poissonian distribution (e.g., Cash 1979; Ryan et al. 2011), with:

$$\phi(M) = 0.4 \ln (10) \varphi^* 10^{-0.4(M-M^*)} e^{-10^{-0.4(M-M^*)}}$$

(4)

For each Schechter function, the best-fit values were taken to be the median of the distribution, with the uncertainty being the central 68% of the distribution. These results are given in Table 4. For the $z = 8$ Schechter function fit, we imposed a top-hat prior forcing $M_{UV}^*$ to be fainter than $-23$. Without this prior, the fit preferred a much brighter value of $M_{UV}^*$, such that the observed data points all lay on the faint-end slope (i.e., a single power law). We discuss the implications of this in §6.6.

Although we computed the volumes down to very faint magnitudes, should we include these faint galaxies and calculate the luminosity function down to $M_{1500} = -17$ or fainter, we would be highly incomplete (Figure 8). In practice, it is our deepest field (the HUDF) which determines how faint we can constrain the luminosity function. The HUDF drops below 50% completeness at magnitudes fainter than $M_{1500} \sim -17.5$ at $z = 4$, 5 and 6, $-18$ at $z = 7$, and $-18.5$ at $z = 8$. Thus, in our calculation of the luminosity function, we only include a given field’s contribution at a given magnitude if it is above the 50% completeness limit for that magnitude and redshift. Extending the analysis fainter will give results dominated by the incompleteness correction.

As shown in Figure 8, while the volume per unit area for the different fields is very tight at $z = 4$, there is a progressively larger scatter apparent when moving towards higher redshift, representing a systematic uncertainty in the effective volume calculation. One likely culprit is the fact that the volumes depend on the distribution of the sizes and colors of objects in a given field. For fields with few sources (i.e., the smallest fields at the highest redshifts), there may be only a single object in a given magnitude bin. To mitigate significant variances in the effective volume at the bright end, where numbers of sources are small, we set the effective volume in a given redshift bin and field in bright bins with less than three objects equal to the value in the brightest bin with more than three objects (i.e., if there are no magnitude bins with more than three objects at $M < -21$, the effective volumes for all brighter bins are set equal to the value at $M < -21$). This change has no discernable effect on our luminosity function results as this is well above the 90% completeness limit for any of our fields, and is thus only done to keep small numbers of galaxies from significantly affecting the volumes.

Another possible issue is the source density of simulated objects. In the smaller fields (HUDE, HUDF parallels, HFF parallels) we input sources with twice the surface density as in the larger fields to speed up the computing time. As some sources (just like real galaxies) will inevitably fall on top of real sources, and thus not be recovered, an increased source density at a given magnitude is then given by

$$C^2(\varphi) = -2 \ln \mathcal{L}(\varphi)$$

(5)

$$C^2(\varphi) = -2 \sum_{i,j} N_{j,\text{obs}} \ln(N_{j,\text{model}}) - N_{j,\text{model}} - \ln(N_{j,\text{obs}}!)$$

(6)

where $\mathcal{L}(\varphi)$ is the likelihood that the expected number of galaxies ($N_{\text{model}}$) matches that observed ($N_{\text{obs}}$) for a given value of $M^*$ and $\alpha$, and $C^2$ is the goodness-of-fit statistic. The subscripts $i$ and $j$ represent the sub-fields and magnitude bins, respectively. The final goodness-of-fit is the sum over all fields and magnitudes in a given redshift bin. We use the effective volume results for a given redshift, magnitude bin, and field to convert from the model number density to the expected number, calculating $\varphi^*$ as the normalization so that the total expected number of galaxies over all magnitude bins matches the total number of observed galaxies.

For each magnitude bin, we performed 10 independent MCMC chains utilizing a Metropolis-Hastings algorithm, each of $10^6$ steps, building a distribution of $M^*$, $\alpha$ and $\varphi^*$ values for each field. During each step of the chain, the likelihood of a given model was computed for each of our observed fields, and then added together to compute the likelihood for the sample as a whole (we also recorded the individual field values, see §6.5). Prior to each recorded chain, we performed a burn-in run with a number of steps equal to 10% of the number in each chain. The starting point for the burn is a brute-force $\chi^2$ fit of a grid of $\alpha$ and $M^*$ values to our data. At the end of the burn, the final values of the parameters from the last step were then the starting points for each chain. The burn-in results were not otherwise recorded. During each step, new values of $M^*$ and $\alpha$ were chosen from a random Gaussian distribution, with the Gaussian width tuned to generate an approximate acceptance rate of 23%. During each step $\varphi^*$ was calculated as the normalization. If the difference between the likelihood of the model for the current step exceeds that from the previous step by more than a randomly drawn value ($\equiv 2 \ln (n)$; where $n$ is a uniform random number between zero and unity), then the current values of the Schechter function parameters were recorded. If not, the chain reverted to the value from the previous step.

By running 10 independent chains, we mitigate against being trapped by local minima in the parameter space. Our final result concatenates these 10 chains together, giving a distribution of $10^6$ values of the Schechter function parameters at each redshift. The results were visually inspected to confirm that the chains reached convergence. For each Schechter function parameter, the best-fit values were taken to be the median of the distribution, with the uncertainty being the central 68% of the distribution. These results are given in Table 4.

density could result in a (slightly) lower completeness. This is just what is observed in these fields, as shown in Figures 7 and 8. To account for this uncertainty, we measured the spread in volume per unit area in each field at $M_{1500} = -21$ at each redshift, which we found to be $\sim 1.5\%$, $3.8\%$, $6.2\%$, $7.8\%$ and $13\%$ at $z = 4$, $5$, $6$, $7$ and $8$, respectively. At each step in the MCMC chain, we perturbed the effective volume by this amount to account for this systematic uncertainty in our luminosity function results.

5.2. Non-Parametric Approach

We have also examined a non-parametric approach to studying evolution in the luminosity function. This is particularly warranted at very high redshift, where the effects responsible for suppressing the bright-end of the luminosity function and causing the exponential decline in number den-
For each magnitude bin and for each field, the likelihood was calculated using Equation 5 above. The actual recorded value of which maximizes the likelihood. While in practice, this yields the best-fit Schechter function parameters at all redshifts we consider here are similar. In this case, as the number densities in the magnitude bins are not linked by an overarching function, we calculate the number density in each magnitude bin independently.

For each magnitude bin and for each field, the likelihood was calculated (using Equations 5 and 6 above) that a given randomly drawn value of $\varphi(M)$ will give the observed number of galaxies. The actual recorded value of $\varphi(M)$ is that which maximizes the likelihood. While in practice, this yields very similar results as one would get by simply taking the observed number and dividing by the effective volume (consistent within a few percent for bins with more than a few galaxies), our approach has two advantages. First, in the limits where numbers are small, this approach is more accurate in that it properly accounts for the Poissonian likelihood. Secondly, this approach generates a full probability distribution for the number densities in each magnitude bin, allowing for the derivation of accurate asymmetric uncertainties. Our SWML luminosity function determinations and best-fit Schechter functions are given in Table 5 and shown in Figure 10.

6. LUMINOSITY FUNCTION INTERPRETATION

6.1. Evolution

As shown in Figure 11, the qualitative shape of the SWML luminosity functions at all redshifts we consider here are similar, in that bright galaxies are rare and faint galaxies are relatively common. Additionally, when examining the Schechter fits (solid line), we see that they are consistent with the SWML determinations. The best-fit Schechter function parameters (Table 4) surprisingly show little evolution in $M^{*}_{\text{UV}}$. However, from $z = 4$ to 8, the uncertainty on $M^{*}_{\text{UV}}$ gets progressively larger, to 0.4 (0.9) mag at $z = 7$ (8). This is easy to understand, as at all redshifts, our dataset contains galaxies in only 1-2 bins brightward of $M^{*}_{\text{UV}}$. Ideally, one would prefer to have multiple bins in magnitude on either side of $M^{*}_{\text{UV}}$ to obtain robust constraints. As shown here, that will require a larger volume than we consider in this analysis. In Figure 11, we also fit the evolution of $M^{*}_{\text{UV}}$ with redshift with a linear function, using our results at $z = 4-8$. We find that $dM^{*}_{\text{UV}}/dz = -0.12 \pm 0.09$; thus, our data do not support a significant evolution of $M^{*}_{\text{UV}}$ with redshift.

We also fit similar functions to see if we detect evolution in $\alpha$ and $\varphi^{*}$. As shown in Figure 11, we do see significant evolution in the faint-end slope $\alpha$, with it becoming steeper at higher redshift, as $d\alpha/\text{dz} = -0.19 \pm 0.04$ (4.4$\sigma$ significance). We see a similar significance in the evolution of the characteristic number density $\varphi^{*}$, which evolves as $d\log \varphi^{*}/dz = -0.31 \pm 0.07$ (4.4$\sigma$ significance). Thus, while $M^{*}_{\text{UV}}$ does not significantly evolve with redshift from $z = 4$ to 8, both $\alpha$ and $\varphi^{*}$ do, in that the number density decreases and the faint-end slope becomes steeper with increasing redshift. In particular, this decline in characteristic number density is by a factor of ~20, over a period of time of less than 1 Gyr. Although the steepening of the faint-end is consistent with previous studies (e.g., Bouwens et al. 2012), the un-evolving $M^{*}_{\text{UV}}$ and strong number density evolution are the opposite of the picture presented in the literature just one year ago (e.g., Bouwens et al. 2011b; McLure et al. 2013). This updated evolutionary picture will be crucial when projecting number counts for future HST and James Webb Space Telescope surveys.

In Figure 12, we show both determinations of the luminosity functions together at all five redshifts, along with the joint confidence contours on $M^{*}_{\text{UV}}$, $\alpha$ and $\varphi^{*}$. It is apparent that there is significant evolution in the luminosity function, with a drop in number density from $z = 4$ to 8, as well as a gradual steepening of the faint-end slope. The position of the “knee” of the luminosity function does not appear to evolve much, consistent with the results above that much of the evolution is in number density and not in magnitude.

6.2. Impact of Magnitude Uncertainties

By definition, our method of computing the luminosity function is dependent on magnitude binning, as we compare the observed number to that expected based on a given model in magnitude bins of width 0.5 mag. While galaxies close
to one side of a magnitude bin have the potential to scatter to another bin, the typical uncertainties on the UV absolute magnitudes of galaxies in our sample are ~0.2 mag. Additionally, galaxies can shift both ways, thus while one galaxy moves out of a bin, another may move in, though this effect will not be symmetric given the shape of the luminosity function. In our results above, we had assumed that magnitude scatter does not significantly impact our results.

To investigate the impact of this assumption, we preformed another iteration of MCMC fitting to our data, here allowing galaxies to scatter between magnitude bins. At each step in the MCMC chain, a new value of $M_{1500}$ was drawn for each galaxy from the 100 SED-fitting Monte Carlo simulation results. The spread in these values encompassed both the photometric scatter in the observed filters and the uncertainty in the photometric redshift (see §3.7). To compare to our fiducial luminosity function values, we recorded both the median Schechter parameter results and the median number density in each magnitude bin, as, unlike our fiducial MCMC run, these varied during each step as the magnitudes changed. At all redshifts, our fiducial values of the step-wise luminosity functions are consistent with these “magnitude-scatter” values within 10% at $M \geq -21.5$, and typically within 2-3%. The sole exception is in the brightest bin ($-22$ at $z = 4$–6, and $-21.5$ at $z = 7$ and 8), where our fiducial number density values are higher by ~15-20% (60% at $z = 7$, where there is only a single galaxy in this bin). We examined the Schechter fit, to see whether this bright-end difference affects our results. Values of both $M^*_{UV}$ and $\alpha$ derived when allowing galaxies to shift between bins are consistent with our fiducial values within 0.1 mag and <3%, respectively. We conclude that the relatively small (~20%) uncertainties in the absolute magnitudes of our galaxies do not have a significant impact on our luminosity function results.

6.3. Non-parametric Evolution

Given that our results show that the Schechter functional parameters may not be a robust method of tracking galaxy evolution (e.g., a non-evolving value of $M^*_{UV}$ does not mean that the galaxy populations are not evolving), we examine the evolution in a non-parametric way. In Figure 13 we show the evolution of the step-wise luminosity function, plotting the number density corresponding to galaxies at $M_{1500} = -21$ and $-19$ versus redshift. From $z = 8$ to 4 the abundance of brighter galaxies increases faster than faint-galaxies. This trend halts at $z = 4$, where bright galaxies have an approximately constant abundance down to $z = 2$, and then turns over. Faint galaxies, however, continue increasing in abundance down to $z = 2$, where they also turn over. This figure highlights the phenomenon of downsizing, where bright/large galaxies grow...
faster at early times (e.g., Cowie et al. 1996, see also Lundgren et al. 2014). This is different from the expectation one would get simply by examining Schechter fits, as the luminosity functions don’t evolve much over the range $2 < z < 4$ (e.g., Reddy & Steidel 2009). Given that the trends here mimic the evolution of the cosmic SFR density, we fit the function provided by Madau & Dickinson (2014) to our data for both number densities, given by

$$\varphi(z) = A \frac{(1+z)^\alpha}{1 + [(1+z)/B]^\gamma} \text{mag}^{-1} \text{Mpc}^{-3}. \quad (7)$$

The evolution with redshift is thus proportional to $(1+z)\alpha$ at low redshift, and $(1+z)^{\alpha-\gamma}$ at high redshift. Fitting the data in this way, we confirm that at $z > 3$, bright galaxies change in abundance faster, as $(1+z)^{9.4\pm0.4}$, than faint galaxies, which go as $(1+z)^{-3.3\pm0.3}$.

Another interesting aspect is to compare the trends observed to our predicted abundance of bright $z = 9$ galaxies (see §9). The trend observed here slightly overestimates our predicted $z = 9$ abundance, though if we assume the uncertainties on our $z = 8$ number density applies to $z = 9$, our trend is consistent with this prediction. In any case, this trend of abundance with redshift lends more weight to our expectation of a significant abundance of bright $z = 9$ galaxies. This figure neglects the impact of dust attenuation, as we are only looking at the observed UV magnitudes. The dust attenuation appears to be luminosity dependent (bright galaxies are dustier than faint galaxies, e.g., Bouwens et al. 2013), as well as being higher at lower redshift. Thus, correcting for dust would not only increase the abundance of bright galaxies more than that of faint galaxies, it would increase it by more at lower redshift, thus enhancing the differences between faint and bright galaxies at $z > 4$.

6.4. Comparison to Previous Results

Our result of a similarly bright value of $M^*_{UV}$ at $z = 6$, 7 and 8 is a dramatic change from previously published results. In Figure 10 we show the step-wise luminosity function results from several relevant studies from the literature. Figure 14 shows our uncertainty results, highlighting both the distribution of $M^*_{UV}$ and $\alpha$ from the MCMC chains, as well as the covariance between the two parameters, along with previous determinations of $M^*_{UV}$ and $\alpha$ (Bouwens et al. 2007, McLure et al. 2009, Ouchi et al. 2009, van der Burg et al. 2010, Bouwens et al. 2011b, McLure et al. 2013, Schenker et al. 2013, Willett et al. 2013, Bowler et al. 2014). In this subsection we compare solely to previous work - we reserve the comparison to the contemporaneous work by Bouwens et al. (2014) to §6.4.1 below.

At $z = 4$ and $z = 5$, both our binned luminosity function data points as well as our Schechter function parameters are in excellent agreement with the ground-based study of van der Burg et al. (2010). We are also in excellent agreement with the ground-based study of McLure et al. (2009) at $z = 5$. We find good agreement with the space-based study of Bouwens et al. (2007) at $z = 5$, but at $z = 4$ the Bouwens et al. (2007) result lies outside our 2$\sigma$ confidence region on the Schechter function parameters, in that we prefer a shallower faint-end slope and a fainter value for $M^*_{UV}$.

At $z = 6$, our binned luminosity function data points are consistent within 1-2$\sigma$ with the Bouwens et al. (2007) results at the faint end. At the bright-end, our data are higher than those from both ground-based studies (though again, typically only different at the 1-2$\sigma$ level). This is somewhat counter-intuitive, as one may expect the ground-based studies to suffer a higher contamination rate, particularly for relatively fainter sources at higher redshift, due to their inability to resolve stars from galaxies, but it may also be explained due to an aggressive sample selection required to minimize contamination. In any case, the differences are not highly significant, with the exception of the brightest data point from Willett et al. (2013), which gives a number density at $M = -22.5$ of $2.7 \times 10^{-8}$ Mpc$^{-3}$. While this is consistent with our upper limit at that magnitude, it is a factor of ~250 lower than our number density only 0.5 mag fainter at $M = -22$ (see Table 5). Given the results at similar magnitudes at lower redshifts, it is highly unlikely that there is such a steep drop in number density over only a 0.5 magnitude interval, though future large area studies can better investigate the difference (Bowler et al. in prep). The larger discrepancy comes when comparing the Schechter function parameters. Specifically, Bouwens et al. (2007) find $M^* = -20.29 \pm 0.19$, and McLure et al. (2009) find $M^* = -20.04 \pm 0.12$. Both values are significantly ($2-3\sigma$) fainter than our derived $M^* = -21.13^{+0.25}_{-0.31}$. For the space-based study of Bouwens et al. (2007), this is understandable, as at that time only optical data were available, thus $z = 6$ galaxies were selected via detections in only one band, and a robust determination of their UV absolute magnitudes was difficult. For the ground-based study of McLure et al. (2009), a cause for the difference is less clear, though certainly the different data being used plays a role.

Comparing to previous works at $z = 7$, we find broadly similar results, in that our results are consistent with the derived number densities from previous studies, yet our Schechter fit prefers a much brighter value of $M^*_{UV}$. This is easier to understand, as a number of previous studies had less data available, and thus, utilizing smaller volumes, were unable to constrain...
the bright end (e.g., Bouwens et al. 2011b; Schenker et al. 2013). The exception is the recent work by McLure et al. (2013), which used a similar volume as our study, though they used the CANDELS UDS field in place of our use of the CANDELS GOODS-N field. Examining the brightest data point from McLure et al. (2013) at $M = -21$, the number density is about a factor of two below our data point. However, the discrepancy is mitigated by two factors. First, as discussed by Bouwens et al. (2014), the use of fixed diameter circular apertures by McLure et al. (2013) systematically underestimates the fluxes for bright, more extended, galaxies. Bouwens et al. (2014) estimate the amplitude of this effect to be $\sim 0.25$ mag. Shifting the brightest McLure et al. (2013) data point by 0.25 mag brings it into agreement with our results. Secondly, the CANDELS GOODS-N field appears to have an overdensity of $z = 7$ galaxies. Specifically, when comparing the number density of $z = 7$ galaxies in the GOODS-N Deep field to the GOODS-S Deep field in Figure 10, GOODS-N has a higher number density at all magnitudes. While we have not selected galaxy samples in the UDS, we can examine this further by recomputing our $z = 7$ stepwise luminosity function using only the GOODS-S and HUDF fields. At magnitudes fainter than $-21$ the results do not change appreciably, as the GOODS-N Deep and Wide fields lie on either side of our Schechter fit at those magnitudes. However, the results using only GOODS-S provide a number density $\sim 33\%$ lower at $M = -21.5$ than our fiducial luminosity function. This difference is at the 1$\sigma$ level due to the large Poisson noise contribution in this bin, and thus is not highly significant.

We also compare to several ground-based studies at $z = 7$. Ouchi et al. (2009) identified 22 bright $z \approx 7$ candidate galaxies over $\sim 0.4$ deg$^2$. Their data points based on detected galaxies are consistent with our own, though their strict upper limits at $M \sim -22$ push their Schechter fit to a fainter value of $M_{\text{UV}}^* = -20.1$, although the large uncertainty (0.76) leaves $M_{\text{UV}}^*$ consistent with our fit at only slightly more than the 1$\sigma$ level. The stepwise luminosity function from Castellano et al. (2010) based on deep HAWK-I data agrees well with our results, while the results from the zFourGE medium band survey of Tilvi et al. (2013) agree at $M = -21.5$, but differ by $\sim 2\sigma$ at $M = -20.5$.

Recently, Bowler et al. (2014) have made a significant improvement in search volume from the ground, discovering 34 luminous $z \sim 7$ galaxy candidates over 1.65 deg$^2$, from the UltraVISTA survey data over the COSMOS field (McCracken et al. 2012) and the UKIDSS survey over the UDS field (Lawrence et al. 2007). Broadly speaking, they are consistent with our results, and they are highly inconsistent with the previous determinations of $M_{\text{UV}}^*$ at $\sim -20$ (Figure 10). There is a mild tension at $M = -21.75$, where the value of

---

**Fig. 14.**—Confidence contours on our measured value of the faint-end slope $\alpha$ and the characteristic magnitude $M_{\text{UV}}^*$ at $z = 4, 5, 6, 7$ and 8, with the light and dark shaded regions denoting 68% and 95% confidence. The large red circles represent our fiducial best-fit luminosity function parameters, while the other colored symbols denote results from previous studies, using the same symbols as in Figure 10 (with the addition of the results from Grazian et al. (2012), shown as the yellow triangle in the $z = 7$ panel, who fit $\alpha$ keeping $M_{\text{UV}}^*$ fixed to $-20.14$). In the $z = 8$ panel, we also show our best-fit result when fixing $\alpha \geq -2.3$ as the white-filled red circle. The histograms to the top and side of each contour plot show the number of MCMC steps when a given value of $M_{\text{UV}}^*$ or $\alpha$ was recorded, with the median value shown by the blue line.
our Schechter fit at that point is $2\sigma$ higher than their derived number density. However, this is their faintest magnitude bin, and is only $\sim 50\%$ complete, thus this data point relieves the most on the completeness correction. In any case, the fact that Bowler et al. (2014) found $z \approx 7$ candidates out to very bright magnitudes gives us confidence that our brighter determination of $M_{\text{UV}}$ is not necessarily dominated by cosmic variance in our fields, but is a true feature of the $z = 7$ universe. However, our present uncertainty on $M_{\text{UV}}$ of $\sim 0.4$ mag makes it apparent that more data is needed to constrain this parameter further.

At $z = 8$, we again find consistent number densities with previous studies, though our larger volume allows us to find more rare, bright ($M = -21.5$) galaxies than observed in some previous surveys, pushing them to lower values of $M_{\text{UV}}$ (though again here our uncertainty on $M_{\text{UV}}$ is large, so the difference in our determination is not significantly different from previous studies). As noted above, in our fit of the $z = 8$ luminosity function, we constrained $M_{\text{UV}}$ to be fainter than $-23$, to avoid un-physically bright values, which tended to be preferred in an unconstrained fit. We note two important points when comparing to previous studies. First, while our study did not utilize the pure parallel BoRG (Trenti et al. 2011) and HIPPIES (Yan et al. 2011) programs, our bright end is consistent with that from Schmidt et al. (2014), based on a determination of the $z = 8$ luminosity function over 350 arcmin$^2$ of pure parallel data (for comparison, our search area at $z = 8$ comprised $\sim 300$ arcmin$^2$; Table 1). The multiple sight-lines of BoRG and HIPPIES leave their results less susceptible to cosmic variance effects, so the agreement implies that cosmic variance may not be strongly affecting our bright end, though we explore this in §6.5.

A potentially larger difference between our results and those of previous studies is also seen at the faint-end, in that our faint-end slope is possibly steeper than previously found. However, our uncertainty is large, such that our result of $\alpha = -2.36^{+0.54}_{-0.39}$ is consistent with previous results of $\alpha \approx -2$ (e.g., Bouwens et al. 2011b; McLure et al. 2013; Schenker et al. 2013). Previous studies use galaxies as faint as $M = -17.5$ in their determination of the faint-end slope at $z = 8$. As discussed above, and shown in Figure 6 we find that we fall below $50\%$ completeness at $M > -18.5$, thus we do not use galaxies fainter than that in our luminosity function determinations. While robust estimates of the number densities of galaxies at $-18.5 \leq M \leq -17.5$ would certainly improve the confidence on the faint-end slope, we use the same deep datasets as the other referenced studies (HUDF). We would expect the incompleteness to be similar between all studies, though it does depend on sample selection and the exact details of the incompleteness simulations. In any case, constraints on the faint-end slope at $z = 8$ should improve in the near future with further data from the Hubble Frontier Fields program. Our inclusion of the Hubble Frontier Fields parallel imaging, even though contributing only a small number of galaxies at $z > 7$, did improve the fractional error on the faint end slope by $2.3\%$ and $7.8\%$ at $z = 7$ and $z = 8$, respectively.

Finally, there have also been theoretical estimates of the luminosity functions at these redshifts, most prominently from Jaacks et al. (2012b), who made predictions in good agreement with our observed luminosity functions. Specifically, their simulations also predict bright values of $M_{\text{UV}}$ of $-21.15$, $-20.82$ and $-21.00$ at $z = 6$, 7 and 8, respectively. They also found quite steep faint-end slopes, of $-2.15^{+0.24}_{-0.20}$, $-2.30^{+0.28}_{-0.18}$ and $-2.51^{+0.27}_{-0.19}$, at $z = 6$, 7 and 8, respectively. Within the uncertainties, these faint-end slopes are consistent with our own, though the apparent agreement at $z = 8$ is tantalizing (though, as mentioned above, we cannot constrain the slope to be so steep). Steep faint-end slopes of $\alpha \approx -2$ at these redshifts were also seen by Salvaterra et al. (2011) and Daval et al. (2013), though both studies also predict a brightening in $M_{\text{UV}}$ towards lower redshift which is no longer observed.

6.4.1. Comparison to Bouwens et al. 2014

Recently Bouwens et al. (2014) submitted a similar study of the evolution of the UV luminosity function at $4 < z < 10$. Their sample of galaxies is larger than ours, as in addition to the datasets we use, they selected galaxies from the CANDELS COSMOS, EGS and UDS fields (though they did not use the HFF parallel fields). The data in these other CANDELS fields have a depth similar to the GOODS-S and N Wide fields, and thus are most useful for constraining the bright-end of the luminosity function. Comparing our results, while the agreement at $z = 5$ is excellent, the Bouwens et al. (2014) data points at $z = 4$ lie at higher number densities than our own for all but the brightest bins. These differences result in a slightly steeper value of $\alpha$ at $z = 4$ ($\alpha_{\text{Bouwens}} = -1.64$ versus $\alpha_{\text{This Study}} = -1.56$), but a significantly brighter value of $M_{\text{UV}}$ ($-21.07$ versus $-20.73$).

Bouwens et al. (2014) also selected galaxy samples at $z = 6$, 7 and 8. Broadly speaking, they found similar results as we do at $z = 6$ and 7, in that previous studies determined values of $M_{\text{UV}}$ which were too faint (Figure 14). However, investigating the actual data points in Figure 10 one can see that at $z = 6$ and 7, the Bouwens et al. (2014) data points frequently lie above our own. This is most significant in the brightest bin of their $z = 7$ luminosity function, which is $1.7\sigma$ higher than our point (interpolating amongst our $M_{1500} = -22$ and $-21.5$ bins to derive a number density at their brightest magnitude of $-21.86$; their data point is $2.2\sigma$ higher if we compare it directly to our $M_{1500} = -22$ data point). At $z = 8$, the Bouwens et al. (2014) data points are more consistent with our own. However, they find both a fainter value of $M_{\text{UV}}$ and a shallower faint-end slope. This is primarily due to their faintest data point, which, at $M = -17.5$, is well below our $50\%$ completeness limit, and lies below the extrapolation of our measured luminosity func-

![Figure 15.](https://example.com/figure15.png)
tion, pushing them to a shallower slope. However, these differences at \( z = 8 \) are not significant, as Figure [14] shows that the Bouwens et al. (2014) results lie comfortably within our 68\% confidence contour on \( \alpha \) and \( M_{\text{UV}}^* \). If we constrained \( \alpha \) at \( z = 8 \) during our fitting to be \( > -2.3 \), we obtain best-fit results similar to Bouwens et al. (2014), Figure [14]. However, given the data at hand, there is no robust justification for such a constraint, thus we do not include this in our fiducial luminosity function fits.

The three CANDELS Wide fields used only by Bouwens et al. (2014) lack space-based \( Y \)-band data, with HST data present in only four filters (\( V_{606}, I_{814}, J_{125} \) and \( H_{160} \)). These fields have deep ground-based optical data, although with much poorer angular resolution, and occasionally shallower depth than available with HST. Of particular worry is contamination by stars and/or brown dwarfs in these samples. The left panel of Figure [15] shows the color-selection plane for galaxies at \( z > 6.5 \) used by Bouwens et al. (2014) in the CANDELS COSMOS, EGS and UDS fields. While the selection space used does include the likely colors of true \( z > 6.5 \) galaxies, it also contains the bulk of M, L and T-dwarf template colors. As shown in the right-hand panel, by adding a single \( HST \) filter, the WFC3 \( I_{105} \)-band, stellar contaminants move out of the selection box, and lower-redshift galaxies move even further from the selection box. To mitigate stellar contamination, Bouwens et al. (2014) used both ground-based \( Y \)-band data, and the Source Extractor stellarity measurement. However, the ground-based data are presently not very deep, with Bouwens et al. (2014) typically only detecting sources with \( Y < 25.5 \) (\( M_{\text{UV}}^* \geq -21.5 \); see §3.4). Additionally, the stellarity measurement can only robustly distinguish point-sources from galaxies much brighter than the detection limit. Our test with the CANDELS \( H_{160} \)-band imaging in the COSMOS and EGS fields show that a robustly identified stellar sequence in the stellarity measurement is only possible at \( H_{160} < 25 \) (\( M_{\text{UV}}^* \geq -22 \)). In light of the apparent overabundance of bright galaxies in the Bouwens et al. (2014) \( z = 6 \) and 7 samples compared to our results, we conclude that the higher quality data in our fields yield more robust and contamination-free measurements of the number densities of bright galaxies in the distant universe.

### 6.4.2. Previously Published Measurement Uncertainties

The differences in results, particularly on the characteristic magnitude \( M_{\text{UV}}^* \) between our current study and previous studies in the literature, are surprising, as in some cases the differences are larger than what would have been expected given previously published uncertainties. In particular, Bouwens et al. (2011b) initially derived \( M^* = -20.14 \pm 0.26 \) at \( z = 7 \). However, the data from Bouwens et al. (2011b) (Figure [10] green triangles), seem insufficient to constrain the bright end to such a relatively high precision. In particular, the evidence for a Schechter-like exponential decline at the bright end does not appear to be present from these early data, which is not surprising as this study was based on data only from the HUDF09 and ERS surveys, which is <20\% of the volume considered in our current work. To investigate this further, we performed another luminosity function fit to our data, using only data from the HUDF09 and ERS fields, finding \( M_{\text{UV}}^* = -20.64 \pm 0.92 \) at \( z = 7 \). Thus, without the CANDELS data, we find a somewhat fainter value for \( M_{\text{UV}}^* \), although fully consistent with our fiducial value, as well as the earlier value from Bouwens et al. (2011b). Likewise, at \( z = 8 \), we find \( M_{\text{UV}}^* = -19.76 \pm 1.40 \); fainter, but consistent with our fiducial \( z = 8 \) estimate. The same is not true for the work of Bouwens et al. (2014), who now find \( M^* = -21.04 \pm 0.26 \) at \( z = 7 \), which is brighter than their previous determination by \( \sim 2.5\sigma \). Understanding the differences in the uncertainty computations between these studies is beyond the scope of our work, but we note that our current MCMC implementation was designed to produce optimal uncertainties on the Schechter function fit parameters. As shown in Figure [11] our current Schechter fit uncertainties are larger than those of Bouwens et al. (2014). While some of these differences may be due to the fact that they used a larger volume (including all five CANDELS fields), the different methods of computing the uncertainties likely play a role.

### 6.5. Cosmic Variance

The impact of cosmic variance on our measurement of the luminosity function is minimized due to our use of several fields, which are split into four widely separated regions of the sky. However, as shown in Figure [16] there is significant variance between the different fields, particularly at \( z \geq 5 \). To estimate the effect of cosmic variance on our derived number densities, we used the QUICKCV calculator provided by Newman & Davis (2002). For a given survey geometry, this program returns the fractional error in a count due to cosmic variance. For this calculation, we estimated the fractional error separately for GOODS-S, GOODS-N, MACS-0416 parallel, and Abell 2744 parallel fields, adding the variances in quadrature to derive a final value of \( \sigma_{\text{CV}} \) for a given redshift bin. In the GOODS-S field, we include the area from the three HUDF09 fields, as even the parallel fields are separated by only a few arcmin from the GOODS-S proper. For the input survey geometries, we estimate rectangular regions of the approximate shape of the GOODS fields, with an enclosed area equal to the GOODS-S Deep+Wide+EARS+HUDF09 fields for GOODS-S, and the GOODS-N Deep+Wide for GOODS-N. The field geometries were thus \( 10.2 \times 15.03 \) for GOODS-S, \( 9.51 \times 14.65 \) for GOODS-N, and \( 2.1 \times 2.1' \) for each of the HFF parallel fields. With these inputs, we find values of \( \sigma_{\text{CV}} \) of 0.111, 0.106, 0.115, 0.124 and 0.133 at \( z = 4, 5, 6, 7 \) and 8. The impact of cosmic variance on our sample is thus at the \( \sim 10-13\% \) level.

To assess the impact of cosmic variance on our measured luminosity functions, we compare this uncertainty to the Poisson noise from our step-wise luminosity functions. At all redshifts, the data at \( M < -21 \) are dominated by Poisson noise (\( M < -20.5 \) at \( z \geq 6 \)), thus we do not expect cosmic variance to be dominating the uncertainties on the bright-end of the luminosity functions derived here. However, cosmic variance may play some role at the faint-end, where we are restricted to small fields. At \( z = 7 \), there does appear to be a step in the stepwise luminosity function at \( M \geq -18.5 \), where the \( M = -19 \) point is below our best-fit Schechter function, and the \( M = -18.5 \) point is above. At \( M \geq -18.5 \) our data come from only the HUDF main field, thus this break represents the point where we become reliant on a small single field. QUICKCV estimates that a single HUDF-sized field at \( z = 7 \) has a cosmic variance uncertainty of 36.2\%. Comparing to our Poisson noise estimate of 30\% uncertainty at \( M = -18.5 \) at \( z = 7 \), cosmic variance may bear some responsibility for this discontinuity in the luminosity function at the faint end. Future measures of the luminosity function at \( M \geq -18.5 \) from the Hubble Frontier Field lensing program may improve these constraints, but while faint galaxies may be found, the vol-
umes will still be incredibly small. Thus, robust constraints on the number densities at this faint level at $z \geq 7$ may need to wait until the James Webb Space Telescope.

We note that the cosmic variance estimates from QUICKCV are for dark matter only, and thus assume a bias of unity. The bright galaxies we observe are likely more biased, thus these estimates are lower limits of the impact of cosmic variance on our results. While multiple fields could in principle allow one to empirically measure the effect of cosmic variance, we have only two independent large fields, thus this is not robustly possible with our current dataset.

6.6. Do the Data Support a Schechter Function?

When allowed to choose any value of $M_{UV}^{*}$, our $z = 8$ Schechter function fit preferred very bright values of $M_{UV}^{*}$, such that all observed data points lay on the faint-end slope part of the function. This implies that the $z = 8$ luminosity function may be consistent with a single power-law. Such a functional form is what one might expect when the feedback effects which govern the bright end at lower redshift (mainly feedback due to accreting supermassive black holes) disappear, or if dust attenuations ceases to be a factor. Bowler et al. (2014) recently postulated that the $z = 7$ luminosity function is better fit by a double-power law, rather than a Schechter form. At $z = 7$, our step-wise data appears consistent with the Schechter fit out to the brightest magnitudes we cover. To see whether our data show a preference for a Schechter functional form at all redshifts, we performed three fits to the data—a Schechter fit, a single power law, and a double power law. To place these fits on equal ground, we found the best-fit parameters for each function using a simple maximum likelihood routine. For the Schechter fit, we use the function shown in Equation 4, investigating a range of $M_{UV}^{*}$ with $\Delta M = 0.1$ mag, and $\alpha$ with $\Delta \alpha = 0.02$. We approximated a single power law using the Schechter functional form with $M_{UV}^{*}$ fixed at $-30$.

For the double power-law, we used the form given in Equation 2 of Bowler et al. (2014), which is similar to the Schechter function at the faint-end, but replaces the bright end with a second power law with slope $\beta$. In all cases, $\phi^*$ is found as the normalization such that the total number of expected objects for a given function is equal to the number observed. The likelihood that a given functional form represents our data is calculated in an identical manner as in §5.1, using Equations 5 and 6.

To compare the results from these fits at each redshift, we used the Bayesian information criterion (BIC). This is similar to a $\chi^2$ statistic, except that it takes into account both the number of data points and the number of free parameters. For a model to be preferred over a competing model, it must have a BIC lower by at least 2. This is sensible, as adding a free parameter must yield a better fit for that model to be preferred. The BIC is calculated as

$$BIC = -2 \ln(L) + k \ln(N)$$  

where $N$ is the number of data points, and $k$ is the number of free parameters (Liddle 2004). For the Schechter, double power law, and single power law fits, the number of free parameters are 2 ($M_{UV}^{*}, \alpha$), 3 ($M_{UV}^{*}, \alpha, \beta$) and 1 ($\alpha$), respectively (we do not count $\phi^*$ as a free parameter as it is a normalization). The number of data points is the number of galaxies in our sample used in the fit, which is restricted to those brighter than the 50% completeness limits discussed above. This gives $N = 2788, 1812, 605, 221$ and 47 galaxies at $z = 4, 5, 6, 7$ and 8, respectively.

The results from this analysis are shown in Table 6. A difference in the absolute value of the BIC of 2 is interpreted as “positive” evidence, while a difference of 6 or higher is “strong” evidence, both in favor of the model with the smaller value. In Table 6, in addition to the value of the BIC, we show the difference between the BIC values for the Schechter

![Image](https://example.com/image.png)
At high redshifts, particularly at the bright end, it is clear that some dust is needed to tighten these constraints, to show whether one can either detect, or rule out a decline at the bright end at \( z = 8 \). If the latter ends up the case, it could indicate either a significant change in the halo masses of bright galaxies, a drop in dust attenuation in bright galaxies, or a change in the physics governing the feedback in bright galaxies in the distant universe.

### 7. COMPARISON TO SEMI-ANALYTIC MODEL PREDICTIONS

In this section we compare our observations with predictions from theoretical models set within the predominant \( \Lambda \) Cold Dark Matter (\( \Lambda \)CDM) paradigm. All such models, whether based on numerical hydrodynamics or semi-analytic techniques, currently rely upon phenomenological “sub-grid” recipes to treat the physics on scales smaller than those that can be directly resolved. These processes include star formation and feedback from massive stars, supernovae, and supermassive black holes. The phenomenological recipes are parameterized and must be empirically calibrated. Here, we compare our new observations at \( z = 4–8 \) with predictions from the models presented in Somerville et al. (2012, hereafter S12). The sub-grid recipes in these models have been calibrated using a set of observations at \( z \sim 0 \), and Somerville et al. (2012) presented a comparison with available observations from \( z \sim 0–5 \). It is therefore very interesting to test these model predictions — with no re-tuning of the free parameters controlling physical processes — in the higher redshift regime probed in this work.

Figure 17 shows our estimates of the rest-UV luminosity function compared with the S12 SAM predictions with and without dust. It is already interesting that the dust-free model predictions are even in plausible agreement with the observations; i.e., the model predictions lie above the observations at all luminosities and redshifts. Next we can ask the question: what characteristics must the dust extinction have in order to

**NOTE.** — The comparison of the Bayesian information criterion statistic for fits to our \( z = 4, 5, 6, 7 \) and \( 8 \) luminosity functions using a Schechter, double power-law and single power law functional form. A difference in the absolute value of BIC between two models of \( \geq 2 \) is positive (strong) evidence for the preference of one model over another. A Schechter function is strongly preferred over a single power law at all redshifts except \( z = 8 \), where our data cannot distinguish between the two models.

versus double power-law, and Schechter versus single power-law. In this formalism, a negative difference is in favor of the Schechter function. Comparing the Schechter function versus the double power-law, we find that a Schechter form is strongly preferred to either a double or single power law at \( z = 4–7 \). This is not surprising, as there is clearly a deficit of observed galaxies at the bright end when compared to the best-fit power law (Figure 10). However, no such deficit is visible at \( z = 8 \), and this is confirmed as both the Schechter fit and the single-power law fit have effectively identical values of the BIC. We conclude that our data support an exponential decline at the bright end of the luminosity function at \( z = 4, 5, 6, 7, 8 \). At \( z = 8 \), we do not see any evidence for a decline in the bright end, at least out to \( M = −21.5 \). Further data are needed to tighten these constraints, to show whether one can
be consistent with the observations? One can immediately see that the dust extinction must be differential with both luminosity (more luminous galaxies are more extinguished) and redshift (galaxies are less dusty at higher redshift). We use a simple approach to model the dust extinction: as in S12, we assume that the face-on dust optical depth in the V-band is given by \( \tau_{\text{V}} = \tau_{\text{dust}} Z_{\text{cold}} / r_{\text{gas}} \), where \( m_{\text{cold}} \) is the mass of cold gas in the disk, \( Z_{\text{cold}} \) is the metallicity of the cold gas, \( r_{\text{gas}} \) is the exponential scale radius of the gaseous disk, and \( \tau_{\text{dust}} \) is a normalization parameter. The values of \( m_{\text{cold}}, Z_{\text{cold}}, \) and \( r_{\text{gas}} \) are predicted by the SAM. We treat \( \tau_{\text{dust}} \) as a free parameter. We then assign random inclinations to our galaxies and use a “slab” model to compute the inclination-dependent extinction (see S12 for details). We use a Calzetti attenuation curve to compute the attenuation at 1500 Å.

In S12, we showed that if we normalize \( \tau_{\text{dust}} \) to match observations at \( z \sim 0 \) and use a fixed value, our model overpredicts the dust extinction at higher redshift. Similarly here, we find that the empirical redshift-dependent function for \( \tau_{\text{dust}} \) adopted in S12 based on observations at \( z \lesssim 5 \) overpredicts the extinction at \( z \gtrsim 5 \). We empirically adjust \( \tau_{\text{dust}} \) to obtain a good fit to the observed LF in the five redshift bins shown, and find that \( \tau_{\text{dust}} \propto \exp(-z/2) \) produces a reasonably good fit over this redshift range, where \( z \) is redshift. This may be physically interpreted as either a changing dust-to-metal ratio, or a systematic evolution in the dust geometry relative to our simple slab model. The required luminosity and redshift dependence of the dust extinction is in qualitative agreement with observational conclusions drawn based on the UV colors (Finkelstein et al. 2012b; Bouwens et al. 2013).

In future work, we plan to investigate whether the dust extinction parameters derived from SED fitting on the observations are consistent with the empirical SAM requirements. In addition, we plan to use these models, which plausibly match the observed UV luminosity functions, to make predictions for the clustering, stellar fractions, and other properties of high redshift galaxies. We will also show the results of varying the sub-grid recipes for star formation and feedback, to illustrate what physical insights can be gained from these observations. For the moment, however, it is intriguing that the models that were developed to explain galaxies at a very different epoch are plausibly consistent with these new observations.

8. EVOLUTION OF THE COSMIC STAR-FORMATION RATE DENSITY

While the evolution of the shape of the luminosity function can provide interesting constraints on the physics of galaxy evolution, the integral of the luminosity function provides a key measure of the total number of UV photons produced at a given redshift. This is a key constraint in two ways. First, the integral of the luminosity function provides a key measure of the total number of UV photons produced at a given redshift (e.g., Madau et al. 1996; Finkelstein et al. 2012a; Robertson et al. 2013). This is approximately the magnitude of the faintest galaxy in our \( z = 8 \) sample, and also facilitates comparison with recent works which use a similar magnitude limit. Galaxies likely exist beyond this magnitude limit (e.g., Trenti et al. 2012; Alavi et al. 2014), which we will consider in the next subsection. We utilized the results of our MCMC luminosity function fitting chain to derive a robust estimate of both the rest-frame UV specific luminosity density (\( \rho_{\text{UV}} \), in units of erg s\(^{-1}\) Hz\(^{-1}\) Mpc\(^{-3}\) ) and its uncertainties. In each case, the chain was calculated by taking the luminosity function from the best-fit Schechter function parameters for that step, and integrating it from \( -\infty \) to \( M_{\text{UV}} \). To convert this number to a SFR density, we use the relation adapted from Kennicutt (1998)\( \rho_{\text{SFR}} = 1.25 \times 10^{-28} \rho_{\text{UV}} \), which converts the specific UV luminosity density to a SFR density (\( \rho_{\text{SFR}} \)), assuming a Salpeter IMF and a constant star-forming population with age \( \geq 100 \) Myr.

**Note.** — All values have been computed down to \( M_{\text{UV}} = -17 \). The dust correction was derived based on the values of E(B-V) derived from SED fitting, with the dust-corrected SFR densities including an uncertainty term from the spread of extinction values at a given absolute magnitude. The SFRs were computed assuming the Kennicutt (1998) conversion from the UV luminosity density (\( \rho_{\text{UV}} \)), assuming a Salpeter IMF, and a constant star-forming population with age \( \geq 100 \) Myr.

Consider the next subsection. While the evolution of the shape of the luminosity function can provide interesting constraints on the physics of galaxy evolution, the integral of the luminosity function provides a key measure of the total number of UV photons produced at a given redshift. This is a key constraint in two ways. First, the integral of the total SFR density provides a key check against the measured stellar mass density (e.g., Bouwens et al. 2013). Secondly, assuming a conversion between UV and ionizing photons, this measure can determine whether galaxies are producing enough ionizing photons to reionize the universe at a given redshift (e.g., Madau & Dickinson 2014). The quoted value of \( \rho_{\text{UV}} \) or \( \rho_{\text{SFR}} \) is the median of the values recorded from all of the MCMC steps, while the 68% confidence range is taken to be the central 68% of values.

Although the UV luminosity is a relatively easy observable in this epoch, the major drawback in its use as a SFR indicator is its susceptibility to attenuation by dust. As a byve of recent work has shown, this dust correction is important even out to \( z \sim 7–8 \) (e.g., Finkelstein et al. 2012b; Dunlop et al. 2013; Bouwens et al. 2013, see also §7). To calculate the total SFR density, we corrected the observed SFR density for extinction using a new iteration of SED fitting, including the deep Spitzer/IRAC data (§3.6), which is a crucial probe of the rest-frame optical light, providing better constraints on the dust attenuation. Using these updated extinction results, we calculated a sigma-clipped median and standard deviation for the best-fit extinction values at a given redshift in four magnitude bins: \(< -21, -21 \text{ to } -20, -20 \text{ to } -19, \text{ and } -19 \text{ to } -17 \). We recover previously observed trends that dust extinction lessens with both increasing redshift and decreasing UV luminosity (e.g., Finkelstein et al. 2012b; Bouwens et al. 2013). The values of \( E(B-V) \) for bright galaxies decreases from 0.15 at \( z = 4 \) to 0.02 at \( z = 7 \), and for faint galaxies from 0.06 at \( z = 4 \), to 0.0 at \( z = 7 \). The small numbers, limited wavelength cover-
Fig. 18.— The evolution of the cosmic star-formation rate density, derived by integrating the best-fit Schechter function at all redshifts to $M_{UV} < -17$. Our data are shown as large circles. To extend this analysis to lower redshifts, we also show the values at $z \sim 2–3$ from Reddy & Steidel (2009), and from $z = 0–2$ from Arnouts et al. (2009). For both studies, we integrated the published best-fit Schechter function parameters to $-17$ to derive the uncorrected values of $\rho_{UV}$. We used the published ratio of the dust-corrected to unobscured values of $\rho_{UV}$ from Reddy & Steidel (2009) to calculate the dust-corrected values at $z \sim 2–3$. At $z \leq 2$, we used the dust correction from Schiminovich et al. (2005), which assumes a constant value of $A_{UV} = 1.8$ at all redshifts. We used Equation 7 to fit the observed trends, deriving the uncertainties on this fit via 10$^5$ Monte Carlo simulations, showing as the shaded region the 68% confidence range from these fits. The total (dust-corrected) SFR density evolves with $(1+z)^{1.3\pm0.5}$ from $z = 3–8$. The green symbols show the high-redshift results from Bouwens et al. (2014) and Oesch et al. (2013), which were not included in the fit, but are consistent with the observed trends at the $\sim 1\sigma$ level.

8.1. Constraints on Reionization

Although it is presently generally assumed that galaxies dominated the ionizing photon budget for the reionization of the IGM, it has been difficult for observations to obtain robust proof. Analyses of the IGM via line-of-sight quasar observations have been able to show that reionization was likely complete by $z \sim 6$ (e.g., Fan et al. 2006, though see Mesinger 2010 and Becker et al. 2014). Additionally, observations of the cosmic microwave background (CMB) radiation constrain the total optical depth due to electron scattering, which, while it cannot directly inform the duration of reionization, it can give an estimate of the reionization redshift ($z_{ion}$) if reionization was instantaneous. The results from the Wilkinson Microwave Anisotropy Probe (WMAP) 9-year dataset give $\tau_e = 0.088 \pm 0.014$, which corresponds to $z_{ion} = 10.6 \pm 1.2$ (Hinshaw et al. 2013).

The primary reason for the current uncertainties in the contribution of galaxies to reionization lies in the uncertainty in the faint-end slope measurements, and also in the assumptions of the escape fraction of ionizing photons ($f_{esc}$) and the clumping factor in the IGM ($\epsilon$). The clumping factor is pri-
Fig. 19.—Left) The specific luminosity density ($\rho_{UV}$) versus redshift (similar to Figure 3 from Finkelstein et al. 2012b). Here we show our luminosity functions integrated down to $M_{V} = -13$ as blue circles. The cyan circles denote the value of $\rho_{UV}$ when we integrate down to our 50% completeness limit ($z = 7$). Recent results from Bouwens et al. (2014) at $z \approx 10$ are shown in green, with the upper and lower squares representing limiting magnitudes of $-17$ and $-13$, respectively. The wide gray curves denote the value of $\rho_{UV}$ needed to sustain a fully reionized IGM at a given redshift, for a given ratio of the clumping factor $C$ over the escape fraction of ionizing photons $f_{esc}$ (Madau et al. 1999). The thin blue curve shows our fiducial value of $C = 3$ and $f_{esc} = 13\%$. Right) The volume ionized fraction, $x_{B}$, of the IGM which can be sustained given the integral of our luminosity functions at $z = 4-8$ (as well as that at $z = 10.4$ from Bouwens et al. 2014). We assume the luminosity function extends to $M_{UV} = -13$, $C = 3$ and $f_{esc} = 13\%$ (this escape fraction is the highest that does not violate constraints set by the Ly$\alpha$ forest at $z \approx 6$; Finkelstein et al. 2012b). We plot constraints on $x_{B}$ from spectroscopy of quasars at $z < 6$ from Fan et al. (2006) and at $z \approx 7$ from Bolton et al. (2011). The blue circle denotes constraints on $x_{B}$ from the evolution in the Ly$\alpha$ luminosity function from $z = 5.7$ to 6.6 from Ouchi et al. (2010), while the blue bar denotes the range of $x_{B}$ values inferred from $z = 7$ follow-up Ly$\alpha$ spectroscopic studies (e.g., Pentericci et al. 2014; Tilvi et al. 2014). The instantaneous redshift for reionization from WMAP (10.6 $\pm$ 1.2) is indicated by the orange rectangle. The derived 50% and 90% $x_{B}$ redshifts from the study of Kuhlen & Faucher-Giguère (2012) are shown in green. The right-hand axis corresponds to the hatched regions, which show the Thomson optical depth to electron scattering ($\tau_{es}$) as predicted by our integrated luminosity functions (blue) compared to WMAP (orange). Compared to previous results, the improved constraints on the luminosity functions yield a tighter range of possible reionization histories. Broadly speaking, we find a picture where the universe is fully ionized by $z = 6$, with the neutral fraction becoming non-negligible at $z \geq 7$, with $\tau_{es}$ consistent within 1.3$\sigma$ of the WMAP9 value.

...mainly constrained theoretically, but most studies agree that it is low ($< 6$) at high redshift (e.g., Faucher-Giguère et al. 2008; Pawlik et al. 2009; McQuinn et al. 2011; Finlator et al. 2012).

To infer from observations of galaxies a number of escaping ionizing photons, one first needs to take the observed UV light, and assume an IMF and a metallicity. Then, to calculate the number of these ionizing photons available for reionization, one then needs to multiply by an assumed value of $f_{esc}$. It is difficult to constrain $f_{esc}$ directly at high-redshift, as the correction for intervening IGM absorption systems is extremely high at $z > 4$. Significant effort is being expended on observationally constraining $f_{esc}$ at $z < 4$. Although bright galaxies at $z \sim 1$ have very low escape fractions (relative to the UV emission) of $f_{esc,rel} < 2\%$ (Siana et al. 2010), escaping ionizing emission has been observed from small fractions of galaxies probed by studies at $z \sim 3-4$ (e.g., Steidel et al. 2001; Shapley et al. 2003; Iwata et al. 2009; Vanzella et al. 2010; Nestor et al. 2011), though some ground-based studies may suffer from contamination by intervening sources (e.g., Vanzella et al. 2012). Recent results imply that escape fractions from star-forming galaxies at $z \sim 2-3$ range from 5–20%, with lower-mass galaxies, especially those with Ly$\alpha$ in emission, having a greater likelihood of having detectable escaping ionizing emission (e.g., Nestor et al. 2013; Mostardi et al. 2013).

Finkelstein et al. (2012a) used measurements of the emission rate of ionizing photons from observations of the Ly$\alpha$ forest in quasar spectra to place an upper limit on $f_{esc}$ from galaxies. Assuming that the rest-frame UV luminosity function extended down to $M_{UV} = -13$, the escape fraction must be $f_{esc} < 13\%$ to avoid violating the Ly$\alpha$ forest measurements of Bolton & Haehnelt (2007). Using this value, and assuming $C = 3$, the luminosity functions available at the time were consistent with a wide range of reionization histories, including an end redshift as late as $z \sim 5$, and an ionized fraction at $z \sim 7$ from 30-100%. Kuhlen & Faucher-Giguère (2012) and Robertson et al. (2013) did similar analyses, folding in additional observables (e.g., the Ly$\alpha$ forest and CMB), found that in order to complete reionization by $z \sim 6$, the luminosity function must extend much deeper than can presently be observed, and/or the average escape fraction must be higher at higher redshift.

Here, we use our updated luminosity functions to reexamine the contribution of galaxies to reionization. Figure 19 shows both the observable specific UV luminosity density ($\rho_{UV}$), which we define to be that above our 50% completeness limit, as well as the total $\rho_{UV}$, which we define as the integrated luminosity function down to $M_{1500} = -13$. We then compare these values to the critical number of UV photons necessary to sustain an ionized IGM at a given redshift, taken from Madau et al. (1999). This figure is similar to Figure 3 from Finkelstein et al. (2012d), thus we refer the reader there for more details. Effectively, these critical curves depend on assumptions about the stellar IMF, metallicity, $f_{esc}$ and clumping factor. The first two are responsible for the conversion from observed UV photons to intrinsic ionizing photons. We assumed a Salpeter IMF, and the width of the curves denote the impact of changing the metallicity from $0.2 \leq Z/Z_{\odot} \leq 1.0$.

We show several curves for the reader’s choice of the ratio of $C/f_{esc}$. Here, we use a fiducial value of $C = 3$ and $f_{esc} = 13\%$,.
consistent with Finkelstein et al. (2012a).

The right panel of Figure 19 shows the ionization history of the IGM, comparing our derived value for the total specific UV luminosity density to our fiducial model of $C = 3$ and $f_{esc} = 13\%$, folding in the values at $z = 10.4$ from Bouwens et al. (2014) to extend our analysis beyond $z = 8$. Our luminosity functions are consistent with a reionization history that starts at $z \sim 11$, and ends by $z > 5$. Although the exact value of the volume ionized fraction in the IGM is uncertain between these redshifts, due to the persistent uncertainty in the faint-end slope, our results imply the following constraints (given the caveat of our assumptions). At $z = 6$, we can constrain $x_{HII} > 0.85$ (1σ), while out to the limit of our observations at $z = 8$ the data are still consistent with a fully ionized IGM (68% C.L. of 0.15 $< x_{HII} <$ 1.0). We find a midpoint of reionization ($x_{HII} = 0.5$) of 6.7 $< z < 9.4$ (68% C.L.).

Broadly speaking, measurements from quasar spectra as well as from Ly$\alpha$ emission from galaxies support a reionization scenario consistent with what we derive (Figure 19). The constraints from Ly$\alpha$ emission are heavily model dependent, and studies claiming a very low value of $x_{HII}$ may be assuming a velocity offset of Ly$\alpha$ from systemic which is too high (e.g., Stark et al. 2014). The one measurement which is in slight tension with our results is that from WMAP9. From our fiducial reionization history, we find $\tau_{\alpha} = 0.063 \pm 0.013$. As can be seen from the juxtaposition of the 68% confidence regions in Figure 19 the tension between the value of $\tau_{\alpha}$ inferred from our results and that measured by WMAP9 is only slight, at 1.3σ.

Future observations are necessary to improve the constraints on reionization from galaxies. Specifically, more robust measurements of the faint-end slope $\alpha$ at $z = 6$–8 can dramatically shrink the uncertainties on $\rho_{UV}$, subsequently reducing the width of our plausible values of $x_{HII}$. Likewise, improving the measurements at $z \geq 9$ will inform us on whether the ionization fraction of the IGM at that early time was significantly non-zero. Even a small contribution ($\sim 10\%$) to $x_{HII}$ at early times will erase any discrepancy between our current observations and those from WMAP. The Hubble Frontier Fields program will improve both of these areas, though definitive results will likely not be obtained until the James Webb Space Telescope (JWST) era.

9. EVOLUTION OF GALAXIES AT $z \geq 9$

Studies of galaxies at $z \geq 9$ are now only in their nascent phase, but HST surveys such as CANDELS and UDF12 are beginning to probe this early epoch. The first robust results on galaxies in this epoch were published by Ellis et al. (2013), who used the new F140W data in the HUDF from the UDF12 program to discover galaxies at $z \sim 9$. This filter allows $z \sim 9$ galaxies to be detected in two bands (F140W and F160W), dramatically reducing the contamination due to noise from F160W-only studies alone (§3.8.1; c.f., Bouwens et al. 2011a). Ellis et al. (2013) discovered the first robust sample at $z > 8.5$, finding seven candidate galaxies. McLure et al. (2013) followed this up with an analysis of the $z = 9$ luminosity function, finding number densities at the faint-end ($M_{UV} \sim -18$) only slightly lower than at $z = 8$. Oesch et al. (2013) also analyzed the $z = 9$ luminosity function, also finding seven $z \sim 9$ candidate galaxies in the HUDF. Although the GOODS-S field lacks the F140W data necessary to detect potential $z = 9$ galaxies in two-bands, Oesch et al. (2013) added the full CANDELS/ERS GOODS-S field to improve their constraints at the bright end. However, they found no $z = 9$ candidates in this larger field. Their published luminosity function is consistent with that from McLure et al. (2013) at the faint end. Bolstered with their additional constraints due to the inclusion of the non-detections from the larger GOODS-S field, Oesch et al. (2013) fit a luminosity function (keeping the faint-end slope and normalization fixed), finding a surprisingly faint value for $M^*_{UV}$ of $-18.8 \pm 0.3$. However, this derivation was based on the assumption that the luminosity function shows luminosity evolution at $z \geq 6$ — a trend which we have now shown to be unlikely. Given this new insight, as well as the presence of a plethora of bright galaxies at $z = 7$ and 8, we consider it likely that the Oesch et al. (2013) estimate of the bright-end of the $z = 9$ luminosity function is underestimated.

A number of recent papers have described empirical evidence that galaxies at high redshift have star-formation histories that increase with time (e.g., Papovich et al. 2011; Salmon et al. 2014; Finlator et al. 2011; Jaacks et al. 2012b; Lundgren et al. 2014). Most recently this has been examined by Salmon et al. (2014), who found that the star-formation rates of galaxies from $z = 3$ to 6 are consistent with a power-law of the form $\Psi(t) = (t/\tau)^{\gamma}$ (with $\gamma = 1.4 \pm 0.1$ and $\tau = 92 \pm 14$ Myr). This analysis assumed that studying galaxies at a constant number density allows one to trace the progenitors and descendants of a galaxy population (e.g., van Dokkum et al. 2010; Leja et al. 2013), and their star-formation history was measured for a constant cumulative number density of $2 \times 10^{-4}$ Mpc$^{-3}$. Although the accuracy of this constant number density technique was initially studied at $z < 3$, recent evidence shows that it likely works out to $z \sim 8$ (albeit it with a possible slight evolution of number density with redshift; Behroozi et al. 2013; Jaacks et al. in prep).

Using our updated luminosity functions, we examine whether the star-formation histories at this earlier epoch are consistent with a similar functional form. Figure 20 shows the cumulative luminosity functions at $z = 4$ to 8 from our analysis. Using the Salmon et al. rising SFH, we can evolve our $z = 7$ cumulative luminosity function back in time to $z = 8$ via:

$$\Psi_{z=8} = \Psi_{z=7} \left( \frac{t_{z=8}}{t_{z=7}} \right)^\gamma$$

where $\Psi$ is the SFR, $t_i$ is the cosmic time elapsed since formation to a given redshift, and using the Kennicutt (1998) conversion between $M_{UV}$ and SFR (with the updated coefficient of 1.25). The available data cannot constrain the formation redshift ($z_f$), as it is degenerate with the star-formation history exponent, thus we assume a value of $z_f = 18$, which gives a close match between predicted and observed $z = 8$ cumulative luminosity functions. Figure 20 shows this predicted $z = 8$ cumulative luminosity function alongside our observed one. A very close match is seen at nearly all magnitudes. Our predicted $z = 8$ data points slightly under-predict the UV luminosity at $M_{UV} > -19$. However, as discussed above, our constraints on the faint-end of the luminosity function at $z = 8$ are tenuous at best. The agreement at the bright-end is excellent. While we did not correct for dust in this analysis, dust is highly unlikely to change these results (particularly at the bright end where we are interested), as bright/massive galaxies at $4 < z < 7$ all have similar UV slopes (Finkelstein et al. 2012b; Bouwens et al. 2013).

It is apparent when examining our cumulative luminosity functions in Figure 20 that this type of evolution will not work
at all redshifts, as our luminosity functions are not uniformly spaced in magnitude (e.g., the $z=4$ and 5, and $z=6$ and 7 cumulative luminosity functions are very close together). We examined one other redshift, evolving the observed $z=5$ luminosity function to $z=6$. We find a decent match, though this under-predicts the bright-end, and over-predicts the faint-end. In any case, as we are most interested in extrapolating to $z>8$, the fact that the predicted evolution works extremely well from $z=7$ to 8 gives us confidence that extrapolating to higher redshifts is reasonable. This assumed evolution is stronger than that observed from $z=6$ to $z=7$. Had we assumed a SFH which matched the evolution from $z=6$ to $z=7$, we would have over-predicted the $z=8$ LF. Our use of a SFH which matches the observed $z=7$ to $z=8$ evolution thus yields a conservatively low $z=9$ predicted luminosity function.

Given the relative paucity of observational information at $z>8$, the fact that our assumed SFH matches the evolution from $z=7$ to 8 makes it interesting to continue our study out to $z=9$. Figure 20 shows the expected $z=9$ luminosity function from our model, alongside our observed luminosity functions at $z=7$ and 8. We calculated the expected $z=9$ luminosity function by again taking the $z=7$ luminosity function and evolving it out to $z=9$ assuming the star-formation history discussed above (and $z_f=18$ for all number densities/magnitudes). As shown in this figure, our predicted $z=9$ luminosity function is consistent at the $\sim 1\sigma$ level with all published data points from McLure et al. (2013) and Oesch et al. (2013). The insignificant under-prediction at the faint end is likely due to the fact that our analysis effectively keeps the faint-end slope fixed to the $z=7$ value, while in reality it may become steeper. Figure 20 shows a Schechter function which matches our predicted $z=9$ luminosity function; we hold constant the value of $\alpha$ and $\Phi^*$ from $z=7$, and find that $M_{UV}=-20.05$ best matches our predicted data. This is more than a magnitude brighter than that reported by Oesch et al. (2013), yet still moderately consistent with the observed data points from both Oesch et al. (2013) and McLure et al. (2013) at the faint end. Using our predicted $z=9$ luminosity function, we would expect to see $4.0 \times 10^3$ galaxies at $M_{UV}<-20.3$ ($H<27$) in a GOODS-sized field. Based on Poisson statistics alone, this is in mild tension with the zero galaxies at these magnitudes reported by Oesch et al. (2013). We also show results from this analysis when evolving $z=7$ to $z=10$, which predict $M_{UV}^*=-19.7$ (or $\sim 1.5$ galaxies per GOODS field).

Recently, Oesch et al. (2014) have performed a new search for extremely distant galaxies, finding four bright $z=10$ candidates in the GOODS-N field and two new candidates from a re-analysis of the GOODS-S dataset. Although as mentioned above, these fields do not have deep F140W data, Oesch et al. (2014) used the $<3\sigma$ detections of these galaxies in the extremely shallow 800s 3D-HST (PI van Dokkum) F140W pre-imaging data to place these galaxies at $z=10$. Even though these galaxies are only detected in one band with $HST^6$, their presence is intriguing. Figure 20 shows the number densities of these sources from Oesch et al. (2014); there is excellent agreement with our predicted $z=9$ evolution, though these data are much higher in abundance than our predicted $z=10$ luminosity function. Although these sources may be at $z=10$ rather than $z=9$, if real, their presence confirms that bright galaxies are relatively abundant at $z>8.5$.

---

6 Oesch et al. (2014) do claim detections of all four of the GOODS-N sources in the IRAC bands, but at least two of these sources are heavily blended with a nearby bright source, and it is unclear whether robust photometry from a faint source can be recovered from such an environment.
Finally, we examine the change in the integrated luminosity density at $z = 9$ with our proposed luminosity function compared to that from Oesch et al. (2012). A change only in $M_{\text{UV}}$ makes little difference in the luminosity density, which is not surprising given the general shape of the luminosity function. However, as shown in Figure 20, our predicted $z = 9$ luminosity function does slightly under-predict the published number densities at the faint end. If we change the faint-end slope to $-2.36$ (to match our $z = 8$ value), we find a better agreement with the published faint $z = 9$ number densities. The luminosity density with this steeper faint-end slope, including our brighter value of $M_{\text{UV}}$ of $\sim 60\%$ higher than that published in Oesch et al. (2012). Thus, it may be that the precipitous decline in the luminosity density (Oesch et al. 2013, 2014) (though see also, e.g., Ellis et al. 2013; Coe et al. 2013) may be less than previously thought (e.g., Ellis et al. 2013; Coe et al. 2013; Behroozi & Silk 2014). While these results are intriguing, we conclude that in order to robustly probe the bright end of the $z = 9$ luminosity function, we require a significantly increased searchable area with the correct filter set (allowing more than single-band detections) to discover these distant galaxies. Constraints on the full shape of the luminosity function in this distant epoch are crucial to design the most efficient surveys with JWST.

10. CONCLUSIONS

Combining the extremely deep data available in the HUDF with the still deep yet much wider data available from CANDELS in the GOODS-South and GOODS-North fields allows robust samples of galaxies to be discovered across a large dynamic range of UV luminosity at $z = 4, 5, 6, 7$ and $8$. Using a robust photometric redshift selection technique, we have discovered a sample of nearly 7500 galaxies at $3.5 < z < 8.5$ over five orders of UV magnitude, and over a volume of $0.6–1.2 \times 10^6$ Mpc$^3$. We discovered a large number of bright ($M_{\text{UV}} < -21$) galaxies at these redshifts, in excess of predictions based on previous estimates of the luminosity functions at $z \geq 6$.

- Our sample selection performs very well when comparing to available spectroscopic redshifts. We perform various tests to estimate the contamination rate, which we find at worst to be $\leq 15\%$, and more likely to be $\leq 5–10\%$. This is consistent with contamination estimates based on the colors of the most likely contaminants, dusty star-forming galaxies at $z \sim 2$. Although the GOODS fields are only two of five CANDELS fields, the remaining three fields contain relatively shallow $Y$-band data, which can result in increased sample contamination, as well as a reduced ability to separate galaxies into $z = 6, 7$ and $8$ samples.

- Our large volume probed allows us to make a robust determination of the amplitude and shape of the bright-end of the luminosity function, which can be used as a crucial probe of the physics dominating galaxy evolution. We used a MCMC technique to estimate the luminosity function, to better characterize the uncertainties, both on the step-wise luminosity function, as well as on the parameters of the Schechter functional form. Our results agree with previous studies at the faint end, but deviate from some previous studies at the bright end, where our data allow us to better constrain the abundance of rare, bright galaxies. We find results consistent with a non-evolving characteristic magnitude ($M_{\text{UV}}^* \approx -21$). Both the faint-end slope ($\alpha$) and the normalization ($\phi^*$) do significantly evolve with increasing redshift, to steeper and lower values, respectively. This is in contrast to previous results, which determined that the evolution of the luminosity function was primarily in luminosity.

- We explored whether a Schechter functional form is required by the data, or whether a single (or double) power-law is a better fit for our luminosity functions; a single power-law form of the luminosity function may be expected at very high-redshift, when dust may not be present, and/or feedback due to AGN activity is no longer sufficient to suppress star-formation in the most massive galaxies. At $z = 6$ and $7$, a Schechter (or double power-law) is required to fit the bright end. However, at $z = 8$, a single power-law provides an equally good fit to the data. Although larger volumes will need to be probed to improve the estimates of the abundances of bright $z = 8$ galaxies, if a power law is preferred, it could imply that we may be observing the era when feedback stops affecting massive galaxies. Comparing to semi-analytical models, we find that the evolution in our luminosity function can be explained by a changing impact of dust attenuation with redshift. In a future work we will explore whether this is a unique constraint, or whether a combination of feedback and dust changes can reproduce the observations.

- We measure the evolution of the cosmic star-formation rate density by integrating our observed luminosity functions to the observational limit of $M_{\text{UV}} = -17$, and correcting for dust attenuation. We find that the cosmic SFR density evolves as $(1+z)^{-3.3^{\pm 0.3}}$ at $z \geq 4$. This smoothly declining function with increasing redshift is consistent with published estimates of the SFR density at $z \geq 9$.

- We investigate the constraints on the contribution of galaxies to reionization by integrating our luminosity functions down to $M_{\text{UV}} = -13$. We find that our fiducial results (assuming $C/f_{\text{esc}} = 23$, which does not violate Ly$\alpha$ forest constraints at $z \leq 6$) are consistent with a reionization history that begins at $z > 10$, and completes at $z \approx 6$, with a midpoint at $6.7 < z < 9.4$. However, the uncertainties, particularly at $z \geq 7$ are high, due to the relatively high uncertainty in the faint-end slope, such that our observations are consistent with an IGM at $z = 8$ that is anywhere from completely ionized, to $85\%$ neutral.

- The presence of bright galaxies at $z = 6–8$ has interesting implications for the luminosity functions at higher redshift. We used empirically derived star-formation histories to evolve our $z = 7$ luminosity function back to $z = 9$, and predict that $\sim 4$ bright ($M_{\text{UV}} < -20.3$) galaxies should be detectable per GOODS-sized field. This is contrary to initial observational results, which, using single-band detections found no bright $z = 9$ galaxies, though consistent with emerging results that some bright galaxies may exist at $z = 10$. Future wider-area studies with two-band detections will provide a more robust estimate of the bright-end of the $z = 9$ luminosity function.
This study highlights the power of combining deep and wide-area studies to probe galaxy populations at very high redshifts, a topic that will remain highly active through the advent of JWST. These results leave us with a variety of questions. What is responsible for the apparent abundance of brightness density fall off dramatically at the high-redshift universe by the end of this decade, allowing us to make full use of JWST?
