ABSTRACT

We report on the 2.5 (400 pc) resolution CO ($J = 1 \rightarrow 0$) observations covering the whole length of the bar in the strongly barred late-type spiral galaxy NGC 7479. CO emission is detected only along a dust lane that traverses the whole length of the bar, including the nucleus. The emission is strongest in the nucleus. The distribution of emission is clumpy along the bar outside the nucleus and consists of gas complexes that are unlikely to be gravitationally bound. The CO kinematics within the bar consist of two separate components. A kinematically distinct circumnuclear disk, <500 pc in diameter, is undergoing predominantly circular motion with a maximum rotational velocity of 245 km s$^{-1}$ at a radius of 1" (160 pc). The CO-emitting gas in the bar outside the circumnuclear disk has substantial noncircular motions that are consistent with a large radial velocity component, directed inward. The CO emission has a large velocity gradient across the bar dust lane, ranging from 0.5 to 1.9 km s$^{-1}$ pc$^{-1}$ after correcting for inclination, and the projected velocity change across the dust lane is as high as 200 km s$^{-1}$. This sharp velocity gradient is consistent with a shock front at the location of the bar dust lane. A comparison of Hα and CO kinematics across the dust lane shows that, although the Hα emission is often observed both upstream and downstream from the dust lane, the CO emission is observed only where the velocity gradient is large. We also compare the observations with hydrodynamic models and discuss star formation along the bar.

1. INTRODUCTION

To investigate the various factors that determine the molecular gas morphology and kinematics in the bars of spiral galaxies, we need to obtain observations of galaxies that have molecular gas in both the nucleus and the bar. NGC 7479 is one of the few galaxies that have abundant molecular gas along most of the bar and in the nucleus (Quillen et al. 1995). It is an isolated, large, strongly barred Sbc galaxy at a moderate distance (32 Mpc, assuming $H_0 = 75$ km s$^{-1}$, a heliocentric velocity of $V = 2371$ km s$^{-1}$, and no correction for the local group velocities; 1" = 160 pc). It has both abundant atomic gas (Laine & Gottesman 1998) and molecular gas (Young & Devereux 1991), and it has been classified as a starburst galaxy based on its large and centrally concentrated 10 $\mu$M flux (Devereux 1989).

We have obtained new, high-resolution (synthesized beam = 2.7 $\times$ 2.1, position angle = $-85^\circ$) 2.6 mm CO ($J = 1 \rightarrow 0$) observations of NGC 7479 and investigate the gas kinematics and distribution in the unusually gas-rich bar. We have detected a strong central molecular gas component and weaker emission along the bar, closely following the leading dust lane, as previously shown by the lower resolution (7") CO maps (Quillen et al. 1995). Our new data have greater sensitivity and spatial resolution. The emphasis in this paper is on the interesting CO kinematics in both the nuclear area and in the offset gas/dust lane along the bar. Other papers in this series address the distribution and kinematics of the neutral, atomic hydrogen gas in NGC 7479 (Laine & Gottesman 1998), the stellar bar pattern speed of NGC 7479 (Laine, Shlosman, & Heller 1998), and the minor merger model for NGC 7479 (Laine & Heller 1999).

2. OBSERVATIONS

The new CO observations were made at the Owens Valley Radio Observatory (OVRO) Millimeter Array. NGC 7479 was observed in three different configurations of the array. The observations were made on 1994 October 7, November 23–24, and 1995 January 18–19. The total integration times at each of the three observed positions and other observing parameters are given in Table 1. The total single sideband temperatures, including the effects of the atmosphere, were typically 350–500 K. Variations in the sky opacity and receiver gain were corrected through measurements of an ambient temperature chopper wheel. The pointing was checked at the beginning of each track, and the strong quasar 3C 454.3 was observed every 19 minutes to

serve as a bandpass and gain calibrator, as well as a secondary flux calibrator.

The calibration followed standard procedures. After correcting for the atmospheric and instrumental gain variations, we produced channel and integrated maps of the CO emission. For mapping the visibility data, natural weighting was used to achieve the highest sensitivity. We used 15 mJy beam$^{-1}$ (1.5 $\sigma$) as the stopping criterion for the CLEAN iterations. The map parameters are given in Table 2. We combined the three observed positions into a mosaic image, correcting for the attenuation of the primary beam. The velocity-smoothed channel maps of the CO emission are shown in Figure 1. The measured line-of-sight CO velocities quoted in this paper are with respect to the LSR unless otherwise stated. The mapped regions have been drawn with large circles in Figure 2, which shows the integrated flux map.

We also present data from H$\alpha$ Fabry-Perot observations, kindly given to us by Stuart Vogel and Michael Regan. These observations were made with the Maryland-Caltech Fabry-Perot Spectrometer (see, e.g., Vogel et al. 1995) attached to the Cassegrain focus of the 1.5 m telescope at Palomar Observatory. The data were obtained on 1994 September 29–30. Forty exposures were taken, each with a 500 s integration time and a pixel scale of 1.98 pixel$^{-1}$. To improve the signal-to-noise ratio, these data have been smoothed to 3.6 spatial resolution. The velocity planes are separated by 12.1 km s$^{-1}$. The velocity uncertainty (rms) is estimated as 1–2 km s$^{-1}$. The data reduction procedure followed that of Regan et al. (1996), who give a more detailed description.

### 3. RESULTS

#### 3.1. CO Flux and Distribution

The integrated $^{12}$CO (1–0) flux map of the whole mapped area and the mean velocity field of the central gas complex are displayed in Figures 2 and 3, respectively. The unit of the integrated flux map has been converted to $N$(H$_2$) cm$^{-2}$ with the “standard conversion factor” (Bloemen et al. 1986; Scoville et al. 1987; Kenney & Young 1989),

$$N(H_2) \text{ cm}^{-2} = 3.0 \times 10^{20} \int T_b(\text{CO})d\nu \text{ K km s}^{-1}. \tag{1}$$

The CO flux spectrum is plotted in Figure 4. The total integrated flux is $266 \pm 40$ Jy km s$^{-1}$, where the stated uncertainty is the rms value in the measured fluxes. In addition, systematic uncertainties in the flux of the secondary calibrator (15%) can lead to a systematic over- or underestimation of the fluxes. For comparison, the total integrated single-dish CO flux for the whole galaxy ($4' \times 3'$) is $1050 \pm 200$ Jy km s$^{-1}$ (Young et al. 1995), but for the

* Assuming a distance of 32 Mpc.

* A 5 $\sigma$ upper limit is given for a point source.
central 45° only, we estimate a CO flux of 430 ± 65 Jy km s⁻¹ (Kenney 1996, private communication).

At least 62% ± 20% of the flux in the central zone of the galaxy has been detected by our high-resolution OVRO interferometer observations. Our interferometer observations have some sensitivity to structures up to 50'' in size, although the sensitivity starts to decrease for structures with sizes larger than half the field of view (structures with sizes > 30''). The "missing" flux could be associated with large-scale structures (> 30'') for which our interferometer measurements are not fully sensitive. However, it is unlikely that a single velocity channel (width = 10 km s⁻¹) would have continuous CO emission structures this large. More likely, our brightness temperature sensitivity (rms = 0.2 K, corresponding to an H₂ column density of about 10^{22} molecules cm⁻² averaged over the beam, using the standard conversion factor) is not good enough to detect the emission from regions with low beam-averaged CO surface densities. We will keep these limitations in mind when discussing the implications of our observations in § 4.
Figu 2.—Naturally weighted integrated map of $^{12}\text{CO}(1-0)$ emission. The contour and gray-scale levels are (4, 8, 16, 32, 48, 96, 144) $\times 10^{21} \text{H}_2$ molecules cm$^{-2}$. The contour around the CO emission is the 17.1 mag arcsec$^{-2}$ level of a K-band image (Quillen et al. 1995), showing the location of the stellar bar. The P.A. of the stellar bar and that of the gaseous bar are different, since the gas is in a leading dust lane. The beam is shown at the bottom right corner of the map. The main CO clumps have been numbered. The beams around the three observed positions have been drawn with large circles.

Figure 2 reveals that all the detected CO emission comes from a nearly linear ridge that is offset toward the leading edges of the bar (assuming the spiral arms are trailing). This ridge has an FWHM value similar to the width of the beam (2.7), indicating that the gas/dust lane is unresolved. The dust lane, as measured from 0.8 resolution optical and near-infrared images, has a width of about 1.5. Therefore, the high-density molecular gas ridge does not have a width larger than that of the dust lane. The CO emission intensity has a strong peak in the nucleus, but overall the emission crosses the nucleus smoothly along position angle (P.A.) $-10^\circ$, connecting the two linear, offset parts of the bar gas/dust ridge.

Applying the standard CO-to-H$_2$ conversion factor and multiplying the resulting masses by 1.35 to account for helium, the molecular mass within the central 1" (160 pc) radius is $3.3 \times 10^8 \, M_\odot$, and the mean gas mass surface density in this area is $4.1 \times 10^3 \, M_\odot$ pc$^{-2}$. This should be compared with the Galactic center molecular gas mass of $3 \times 10^7 \, M_\odot$ within the central 500 pc (Dahmen et al. 1998), which has an average molecular gas surface density of 150 $M_\odot$ pc$^{-2}$. The corresponding hydrogen column density in the nucleus of NGC 7479 is about $1.6 \times 10^{23}$ cm$^{-2}$, which implies a beam-smoothed optical extinction ($A_V$) value of almost 100 mag. Extinction will be further discussed when addressing the star formation rates (SFRs) in § 4.2. The molecular gas mass in the central 7" diameter region is about $2 \times 10^9 \, M_\odot$, and the total molecular mass derived from our observations is $4 \times 10^9 \, M_\odot$. Roughly half ($2 \times 10^9 \, M_\odot$) of the detected flux (and mass) lies along the bar outside the central 7" diameter region.

The detected CO emission along the bar is highly clumpy. In the integrated flux map (Fig. 2) at least six separate clumps in addition to the nuclear gas complex can be identified. The masses of the clumps along the bar range from $9 \times 10^6 \, M_\odot$ to $2 \times 10^8 \, M_\odot$. However, the use of the standard CO-to-H$_2$ conversion factor may not be justified in
strongly shocked gas along the bar. The temperature and density are likely to be higher in the shock, although these effects tend to offset each other. If the clouds in the shock are not gravitationally bound (see § 4.1.2), their large line widths cause the standard CO-to-H$_2$ conversion to overestimate the H$_2$ mass. Shock chemistry can also change the conversion factor. The lower limit for the conversion factor is obtained for optically thin CO emission, which has a conversion factor 20 times smaller than the standard factor (see Bryant & Scoville 1996). Overall, it is difficult to ascertain how the conversion factor would change in bar shocks.

The sizes of the clumps along the bar are too large to be individual self-gravitating giant molecular clouds but their sizes and masses are similar to those of giant molecular associations (GMAs) found in the nearby spiral galaxies M51, M100 (Rand 1993a, 1993b, 1995), and NGC 4414 (Sakamoto 1996). However, the clumps in NGC 7479 are kinematically very different from those observed in the other galaxies (§ 4.1.2).

The azimuthally averaged radial profile of the molecular gas is compared to the radial profiles of R- and K-band light, H$_\alpha$, H I, and $\lambda = 21$ cm radio continuum emission in Figure 5. The optical and near-infrared images were first smoothed to the spatial resolution of our CO data (2.5'). However, the radio continuum and the H I data (from Laine & Gottesman 1998) have resolutions of 4' and 15', respectively.

Within the central 7' the CO emission intensity rises by more than an order of magnitude, as in NGC 3504 (Kenney, Carlstrom, & Young 1993). Unlike NGC 3504, the R- and K-band profiles are shallower than the CO profile in this area. This may reflect the lack of an intense starburst in the...
nucleus of NGC 7479, its relatively small bulge component, or large extinction. The CO-to-Hz intensity ratio is approximately constant in the central 2', where the nuclear gas disk lies, as in NGC 3504 (Kenney et al. 1993). Outside this inner region NGC 3504 and NGC 7479 show opposite behaviors: in NGC 3504 the Hz gradient becomes steeper than the CO intensity profile, whereas in NGC 7479 the opposite is true. This could mean that the star formation efficiency increases outward from the center in NGC 7479. Unfortunately, there are no suitable radio continuum measurements that would allow us to assess the effects of extinction. In other galaxies comparisons between the 6 cm thermal emission and Hz have shown that extinction can change the “picture” (e.g., M100; García-Burillo et al. 1998).

The radio continuum emission is very strongly peaked in the nucleus. These data are shown at 4' resolution, so the gradient at a higher resolution is likely to be even larger. If the radio continuum is regarded as a star formation tracer, the star formation efficiency decreases with radius as in NGC 3504. However, the nucleus of NGC 7479 is slightly active (LINER), and the radio continuum may also have a contribution from the nucleus unrelated to star formation.

Figure 5b shows the striking difference in the distribution of H I and CO emissions. It should be noted that our CO observations did not extend very far out into the spiral arms of NGC 7479. The atomic gas appears to have been converted into the molecular form at the higher pressures of the central potential well, aided by the self-gravity of the gas.

3.2. Gas Motions

The line-of-sight velocity field (Fig. 3) is complex and difficult to interpret. The contours in the nuclear few arcsec region are aligned perpendicular to the P.A. of the outer disk (22'; Laine & Gottesman 1998), consistent with solid body rotation. Beyond a 3' radius in the south, the line-of-sight velocity contours are aligned roughly along the bar. This morphology of the velocity field is consistent with a large radial velocity component (along the bar; e.g., Lindblad, Lindblad, & Athanassoula 1996). The northern part of the bar does not have a sufficiently extended emission region in which we could estimate the character of the gas motion.

The central 4'' region of the velocity field where the circularly rotating gas and the gas flowing along the bar meet has a Z shape. To better understand the gas motions in the bar, we have made position-velocity plots at several different P.A.'s and spatial locations.

Position–velocity plots close to the major axis (at P.A. 25') and along the bar are presented in Figures 6 and 7, respectively. Both plots are centered at the nuclear CO emission peak (R.A. 23h02m26s.37, decl. 12°03'11.1''; B1950.0) as determined from the map of integrated CO emission (Fig. 2), and they represent planes (width 0.5) of the original data cube. Outside the central 2' region, the mean CO velocity within each emission region along the bar does not deviate from the mean velocity (2360 km s⁻¹) of the nuclear region by more than 50 km s⁻¹ (Fig. 7). Figure 7 also has a line that indicates the location where emission would be expected if it followed the rotation curve derived from the gravitational potential, obtained by converting the K-band surface brightness into a mass surface density (Quillen et al. 1995). Since Quillen et al. (1995) did not consider the three-dimensional nature of the bulge, and the M/L ratio as determined from a K-band image may be variable near the nucleus, the gravitational potential and the rotation curve in the central 8'' are uncertain.

The remarkable departures of the observed emission from the expected location traced by the line in Figure 7 outside the nuclear region indicate that the gas motion along the bar is inconsistent with pure circular rotation. Assuming that the northwestern side of the galaxy is the near side (spiral arms trailing) and that there are no substantial vertical motions, it is possible to make a rough estimate of the radial velocity of the gas along the bar, taking the tangential speed of the gas in the bar from the bar rotation rate. There will be an additional component of tangential speed, but if the gas is captured in orbits that are elongated along the bar, a first-order estimate of the tangential velocity is provided by the bar pattern speed. Using the bar pattern speed of 27 km s⁻¹ kpc⁻¹ (Laine et al. 1998), the tangential velocity at the distance of 15' (3.2 kpc) is 65 km s⁻¹. The observed velocity at this point in the clump north of the center is only slightly higher, 2370 km s⁻¹, than the velocity of the nucleus. Accounting for the difference between the directions of the gas bar major axis and the line of nodes (about 31°) and the inclination (51°; Laine & Gottesman 1998), the observed emission velocities can be reproduced with a radial inflow component of 110 km s⁻¹.

The plot along the CO major axis (Fig. 6a) also gives a hint of the existence of two separate kinematic components. The first component shows up as a large linear velocity gradient across the central few arcsec (190 km s⁻¹ arcsec⁻¹ or 1.2 km s⁻¹ pc⁻¹), which is consistent with solid body rotation. After correcting the observed velocities for the inclination, the maximum rotation velocity in the nuclear disk is 245 km s⁻¹ at a radius of 1'. The noncircular kinematic component can be seen as extensions toward lower declinations and lower velocities (marked “E1” in Fig. 6a) and higher declinations and higher velocities (marked “E2” in Fig. 6a).

We have also made position-velocity maps perpendicular to the bar (at P.A. 90°) at several positions along the bar, using both the CO and the Hz data cubes. The resulting maps, together with an image of the integrated CO and Hz...
emissions, are shown in Figure 8. The fluxes between the horizontal boundaries indicated in the map were summed together to improve the signal-to-noise ratios within every numbered region. The velocity resolutions are 10.4 km s\(^{-1}\) (CO) and 12.1 km s\(^{-1}\) (H\(_\alpha\)).

The overlay of the total CO intensity (at 2.5 spatial resolution) contours on an H\(_\alpha\) image (at 0.8 spatial resolution, kindly given to us by J. Knapen) reveals that the CO and H\(_\alpha\) emission peaks occur mostly at the same locations within the available spatial resolution. However, in regions 3 and 7, the H\(_\alpha\) emission maxima are at a larger radius and larger distance from the bar major axis than the CO maxima. The position-velocity maps show that in H\(_\alpha\), two velocity “plateaus” of emission, both upstream and downstream from the dust lane, are connected by a steep CO (and H\(_\alpha\)) velocity gradient. Strong CO emission only exists in the region of the steep velocity gradient.

The largest velocity gradient in the CO position-velocity maps presented in Figure 8 is about 240 km s\(^{-1}\) arcsec\(^{-1}\) in region 7. Correcting this for the inclination gives a gradient of 1.9 km s\(^{-1}\) pc\(^{-1}\). The least steep gradients further out along the bar have values around 0.5 km s\(^{-1}\) pc\(^{-1}\).

4. DISCUSSION

4.1. Gas Flow and Molecular Gas in the Bars
4.1.1. Comparison of Observations and Models

Observations of NGC 7479 show dust lanes displaced toward the leading edges of the bar, accompanied by CO emission (Fig. 10) that traces dense compressed molecular material. The large velocity gradients that we see in our observations occur along these gas/dust lanes. This is consistent with the general expectation of shocks in the compressed interstellar medium (ISM). In shocks the component of velocity perpendicular to the shock has an abrupt change in magnitude. The large velocity gradients in our observations are also consistent with the models that show that gas streaming along the bar has an apogalacticon near the bar dust lanes, where the gas flow changes from having a radially outward-directed velocity component to having a radially inward-directed component (see, e.g., Fig. 5 in Roberts, Huntley, & van Albada 1979). The line of sight at which the bar in NGC 7479 is observed is intermediate between perpendicular and parallel to the bar, and it is thus favorable for seeing the large gradients in the line-of-sight velocity across the bar dust lanes.

Figure 9 shows position-velocity maps from observations and from a smoothed particle hydrodynamics (SPH) bar flow model (Laine et al. 1998). The position-velocity slices in both the observations, and the models were taken across the bar at the same distances from the nucleus and are thus directly comparable. The model data were taken from the run with the best-fitting bar pattern speed (27 km s\(^{-1}\) kpc\(^{-1}\)). The two-dimensional simulation frame was projected to the orientation of NGC 7479 (inclination 51°, P.A. 22°; Laine & Gottesman 1998; the angle between the stellar bar and the kinematic major axis in the plane of the galaxy 25°). The spatial resolution of the model was
Fig. 8.—Overlay of the CO emission intensity on a gray-scale image of the Hα emission (left). (The 0.8 resolution Hα image was kindly given to us by Johan Knapen.) The contours of the CO emission are given at 40, 120, 280, 360, 440, 600, 760, 920, 1080, 1240, 1400, 1560, 1720 atoms cm$^{-2}$, using the standard conversion factor between CO intensity and H$_2$ surface density. The regions in which the emissions were integrated for the position-velocity maps are separated by solid lines and numbered from 1 to 8. The corresponding position-velocity maps are shown on the right, the first column giving the Hα maps, the second column showing the CO maps, and the third column showing both overlaid, using gray scales for the Hα emission. The velocities are heliocentric. The contours on the position-velocity maps are fractions of the peak intensity in a map, chosen to give a clear presentation of the emission. The strongest CO and Hα emission occurs in a narrow ridge with a large velocity gradient. Weaker Hα emission is also observed both upstream and downstream from this ridge.
smoothed by a Gaussian to 2.5 (400 pc), and the velocity was sampled at 10.4 km s\(^{-1}\) bins, comparable to the CO (and, roughly, the H\(\alpha\)) observations.

SPH represents total gas, and therefore it traces both the compressed regions of dust lanes and dense molecular gas as well as the more diffuse ionized gas. In both the models and the observations (Figs. 7–10), the observed velocity changes by about 150–200 km s\(^{-1}\) across the highest gas concentrations (which in optical and near-infrared observations are seen as a dust lane; Fig. 10), but the H\(\alpha\) emission “plateaus” upstream and downstream from the dust lane have relatively small velocity gradients. Our kinematical results support the expectation that the bar dust lane traces shocks in the gas flow.

The models also show the velocity “plateaus” of gas upstream and downstream from the location of the large velocity gradient. The downstream “plateaus” suggest that some fraction of the gas has moved out of the shock region. However, the mean velocity of the shock regions is consistent with radial inflow motion, as mentioned in § 3.2. Therefore, apart from gas that appears to have moved downstream away from the shock front, our observations are consistent with the picture given by Regan, Vogel, & Teuben (1997, hereafter RVT; see also Regan 1996), who claim that all gas that encounters the dust lane subsequently flows down the dust lane into the nuclear region.

Our observations and the comparison to the SPH model have shown that the response of gas (including molecular) to the forces along the bar in NGC 7479 is more consistent with the behavior of dissipative diffuse gas under hydrodynamic forces (pressure, viscosity) than the response of giant dense molecular gas clouds that might be expected to react like a ballistic particle. Both the grid-based ideal gas hydrodynamic codes and SPH codes have modeled gas flows, including the compression regions or shocks, satisfactorily in most cases. “Sticky particle” (SP) codes smear the shocks over relatively large spatial scales, depending on the particle size, and they may have difficulties modeling the 100 pc scale, steep velocity gradients in the bar dust lane of NGC 7479. It is unclear at present which code is the most realistic.
in modeling the behavior of the ISM. The equation of state of the ISM is unknown, and the multiphase numerical modeling of the gas has not been done yet.

4.1.2. Properties of Molecular Gas in the Bars

The star formation and gas flow properties along bars would be easier to understand if the physical state of the CO emitting regions were known. Specifically, we would like to know if the CO-emitting regions are gravitationally bound. RVT claim that the excellent agreement between their observations of NGC 1530 and the hydrodynamic models based on diffuse ideal gas suggests that the gas they traced with Hα kinematics is diffuse gas and not concentrated in gravitationally bound giant molecular clouds (GMCs; masses up to a few times $10^6 \, M_\odot$) or even larger and more massive GMAs, which might behave more like ballistic particles than diffuse gas. Our observations and the comparison to models also suggests that the molecular gas in the bar of NGC 7479 does not behave like ballistic particles. In the disk of spiral galaxies the situation appears different, as complexes of GMAs have been found in at least the nearby galaxies M51 (Rand 1993a, 1993b; Vogel, Kulkarni, & Scoville 1988), M100 (Rand 1995), and NGC 4414 (Sakamoto 1996).

The CO luminosities (masses) and diameters of the CO emission regions along the bar in NGC 7479 are roughly similar to those seen in the disks of other spirals such as M51, but the kinematics along the bar of NGC 7479 are very different. NGC 7479 has very large velocity gradients of $1.9 \, \text{km s}^{-1} \, \text{pc}^{-1}$ across the emitting regions. Therefore, the CO emission regions along the bar are unlikely to be self-gravitating.

The virial masses of the CO emission regions in $M_\odot$ can be roughly estimated from

$$M_{\text{vir}} = 550D(\sigma_{1D})^2$$

(Rand 1993a; Scoville & Sanders 1987). Here $D$ is the observed FWHM diameter in pc, and $\sigma_{1D}$ is the one-dimensional velocity dispersion in km s$^{-1}$. This formula assumes a $1/r$ density profile for the gas within a GMA. The mass required for the GMA to be self-gravitating is half of this mass. Using a velocity dispersion of $150 \, \text{km s}^{-1}$ and an FWHM diameter of 150 pc (about 1'), the resulting virial mass is about $2 \times 10^9 \, M_\odot$. For comparison, the observed masses of the clumps along the bar (assuming the standard conversion factor) range from $9 \times 10^6$ to $2 \times 10^8 \, M_\odot$. Thus it is unlikely that the CO gas concentrations that lie along the bar are virialized or even gravitationally bound.

4.2. Star Formation in the Bar of NGC 7479

SFRs from the Hα fluxes in the offset gas and dust lane along the bar have been calculated from

$$\text{SFR}_{\text{H}_\alpha} = 7.07 \times 10^{-42}L(\text{Hz}) \, M_\odot \, \text{yr}^{-1},$$

(Bushouse 1987; see also Kennicutt 1983). Equation (3) assumes a Salpeter initial mass function (IMF) down to stars of mass 0.1 $M_\odot$ and up to stars with masses of 100 $M_\odot$. The Hα fluxes have not been corrected for extinction, so the SFRs from equation (3) are lower limits. The integrated SFR in the bar region is around $0.2 \, M_\odot \, \text{yr}^{-1}$. Uncertainties due to extinction and the choice of the IMF with its cutoffs are discussed in Bushouse (1987). Specifically, Bushouse compared the global SFRs as calculated from the Hα fluxes (uncorrected for extinction effects) to
global far-infrared fluxes. The latter were found to be 3 times larger on average, and therefore an average extinction correction factor of 3 applies to isolated galaxies. For comparison, Martin & Friedli (1997) measured the ratio of the Hz and Hβ lines in a few selected H II regions along the bar and obtained a bar extinction value of 0.8 mag in Hβ, which corresponds to a factor of 2. Multiplying the measured Hz flux by 2.5 results in an SFR(Hz) of 0.5 $M_\odot$ yr$^{-1}$ along the bar of NGC 7479, comparable to the value (0.4 $M_\odot$ yr$^{-1}$) obtained by Martin & Friedli (1997). The SFR for the whole galaxy, calculated from the infrared luminosity [L(IR); 8.9 $\times$ 10$^{10}$ L$_\odot$; Young et al. 1989], is about 45 $M_\odot$ yr$^{-1}$ [SFR(IR) = 1.34 $\times$ 10$^{-43}$ L(IR); Hunter et al. 1986; Bushouse 1987], 90 times larger than the SFR along the bar and thus largely not seen in optical tracers (although the Hz luminosity of the bar region is only about 10% of the total Hz luminosity of NGC 7479).

Bushouse (1987) finds that SFR(IR) is 3–6 times larger than SFR(Hz) among normal galaxies, (3 times in isolated galaxies and 6 times in interacting galaxies), most likely because of extinction in the optical. Yun & Hibbard (1998) confirmed the significantly larger SFR(IR) values and also found that the Hz component seen in the nuclear starburst systems is dominated by the starburst superwind and scattered emission. It is possible that the nucleus of NGC 7479 hosts a starburst behind dozens of magnitudes of optical extinction. About 15% of the 21 cm continuum emission is concentrated in the central beam (4.3 $\times$ 3.85), giving a rough size scale for the starburst region (Laine & Gottesman 1998).

The large velocity gradient of 0.5–1.9 km s$^{-1}$ pc$^{-1}$ across the bar dust lane of NGC 7479 is likely to be dynamically important and affect star formation. The large velocity gradient can prevent large gas concentrations within the bar dust lane from being self-gravitating, as indicated by our simple calculation in §4.1.2.

The kinematical conditions in the bar dust lane are quite different from those in the spiral arms of M51, which has unusually strong spiral density waves with small pitch angles. Although there is a density-wave–induced velocity gradient of 0.05–0.1 km s$^{-1}$ pc$^{-1}$ across the front half of the spiral arms of M51 (Vogel et al. 1988; Rand 1993a), this gradient is an order of magnitude smaller than that in the bar of NGC 7479, and it is furthermore in a direction that reduces the amount of shear that otherwise occurs in a disk with a flat rotation curve.

Thus, in spiral arms the largest concentration of dense gas and the regions of reduced shear occur in the same places, and both effects increase the susceptibility of gas to gravitational collapse. In bars the largest concentration of dense gas occurs in a region of a large velocity gradient, and this opposes the susceptibility of gas to gravitational collapse.

This could be the reason why star formation is observed upstream and downstream from the dust lane as well as within it. Although the regions upstream and downstream from the shock front have lower gas density, their smaller velocity gradients may enable star formation. As discussed in §3, the regions upstream and downstream may have molecular gas that has a column density that is too low to be detected when averaged over the synthesized beam, but the density may be high enough to enable star formation, making it easier to understand the wide distribution of Hz emission across the bar.

The regions with the highest gas density are regions with the largest velocity gradients. Although stars are certainly forming in this dense dust lane gas, the SFR may be limited by the large velocity gradients: the long timescale for star formation along the bar (2 $\times$ 10$^9$ $M_\odot$ yr$^{-1}$ = 4.0 $\times$ 10$^9$ yr) implies that the bar gas is not experiencing a starburst. Again, this conclusion is subject to the effects of extinction, as discussed before, although these effects are unlikely to change the basic conclusion. Elmegreen (1979) and Kenney & Lord (1991) have also suggested that the tidal forces on the gas clouds along the bar dust lanes may inhibit star formation.

4.3. Nuclear Gas Mass Fraction

The molecular gas mass in the centers of some spiral galaxies is a large fraction (up to at least 50%) of the total dynamical mass (Turner 1994; Kenney 1997). Under these conditions, the self-gravity of the molecular gas becomes important and may drive further inflow toward the center (Shlosman, Frank, & Begelman 1989; Shlosman, Begelman, & Frank 1990; Heller & Shlosman 1994; Knappen et al. 1995; Wada & Habe 1992). The gas mass fraction in the central disk of NGC 7479 can be calculated in the region that exhibits circular rotation, using the standard CO luminosity to H$_2$ mass conversion factor. The rotation velocity in the center is about 245 km s$^{-1}$. We use a radius of 1' for the nuclear gas disk. Using a distance of 32 Mpc, the total dynamical central mass becomes

$$M_{dyn} = \frac{rv^2}{G} = 2.2 \times 10^9 M_\odot .$$ (4)

The molecular mass in this area is $3.3 \times 10^8 M_\odot$, or 15% of the dynamical mass. The molecular gas mass is a considerable part of the total mass in the center, although it does not dominate the dynamics. If the rest of the mass is stellar, the average mass-to-luminosity ratio in the K-band in this central area is 0.7 in solar units. This would imply a relatively young (a few Gyr) stellar population or, alternatively, a metal-rich old population (Worthey 1994).

Since the SFR along the bar is 0.5 $M_\odot$ yr$^{-1}$ and the gas inflow rate is at least 4 $M_\odot$ yr$^{-1}$ (Quillen et al. 1995; Laine 1996), most of the gas presently in the bar region should reach the circumnuclear region before it turns into stars. The uncertainties are caused by the unknown amount of extinction, which may severely suppress the observed Hz fluxes along the bar dust lane and cause an underestimate of the bar SFR. The net inflow of $2 \times 10^9 M_\odot$ of gas would double the nuclear mass in less than a Gyr, meaning that NGC 7479 is in a short-lived evolutionary state. The resulting increase in the nuclear mass would likely drive the evolution of the galaxy toward an earlier Hubble type (Kormendy 1993; Friedli & Benz 1993; Kenney & Jogee 1997).

5. Conclusions

The high spatial resolution CO observations of NGC 7479 together with Hz data have shown the gas distribution and motions in a dynamically young barred spiral galaxy (see Kenney & Jogee 1997; Laine & Heller 1999). Our main conclusions are summarized in the following:

1. The CO emission has a strong central peak, but about 50% of the emission comes from regions outside the nuclear
zone, mostly from a clumpy distribution along the bar dust lane.

2. The bar dust lane and the CO gas emission occur at the same locations within the resolution of the observations.

3. The CO velocity field is consistent with circular rotation only in the central 2′ (300 pc) diameter region. Outside this region, the velocity field deviates strongly from pure rotation, and the velocities must have a substantial (at least 100 km s\(^{-1}\)) radial component along the bar.

4. The CO emission across the bar dust lane has a large velocity gradient (up to 1.9 km s\(^{-1}\) pc\(^{-1}\)) with a projected velocity change up to 200 km s\(^{-1}\). The Hz emission shows a similar large gradient, but it also has “plateaus” of constant velocity emission both upstream and downstream from the large velocity gradient. The large velocity gradient is consistent with combined effects of a shock and a change in the radial direction of gas streamlines in the bar dust lane.

5. The gas clumps along the bar have masses from 9 × 10\(^6\) to 2 × 10\(^8\) M\(_\odot\) if the standard CO-to-H\(_2\) conversion factor is assumed. However, the large velocity gradient across these complexes in the bar dust lane makes this assumption suspect.

6. No strong CO emission exists in the bar region outside the dust lane, and the gas complexes in the dust lane are unlikely to be gravitationally bound because of the large velocity gradients across them.

7. Based on the relative strengths of the CO and Hz emissions in the nucleus and along the bar, we conclude that either the optical emission from the nucleus is strongly reduced by extinction or the star formation efficiency in the nucleus is lower than in regions along the bar.

8. The star formation timescale along the bar is long, a few Gyr. The large velocity gradients in the bar dust lane may prevent the bar gas from forming stars more rapidly.

9. Along the bar, the gas inflow rate of 4 M\(_\odot\) yr\(^{-1}\) is much greater than the SFR of 0.5 M\(_\odot\) yr\(^{-1}\), implying that most of the gas presently in the bar will reach the circumnuclear region. If that happens, within the next ~ 1 Gyr the central mass of NGC 7479 should roughly double. However, extinction in the bar dust lanes and in the nuclear region causes the cited SF rate to be a lower limit, and the actual amount of gas reaching the circumnuclear region is likely to be lower.

10. The nuclear gas mass fraction is likely to be at least 15% of the total dynamical mass within the central gas disk, and, therefore, the molecular gas affects the dynamics in the nuclear disk.

We are very grateful to Nicholas Z. Scoville for financial support for the publication of our results and the observing run. We are grateful to Michael Regan and Stuart Vogel for providing us with the Hz data for comparison with our CO data. We thank P. Martin, D. Friedli, A. Quillen, and J. Knappen for providing most of the optical and near-infrared broad-band and Hz images used in this work. UKIRT is operated by the Joint Astronomy Centre on behalf of the United Kingdom Particle Physics and Astronomy Research Council. Some of the data reported here were obtained as part of the UKIRT Service Programme. S. L. acknowledges D. S. R. at the University of Florida for financial support and I. Shlosman for helpful discussions on bar dynamics. We thank the anonymous referee for comments that improved the paper. This work was supported in part by NSF grant AST 93-14079.
