Abstract: This paper describes a method whereby a governmental policy maker can discover where policy statements are discussed, and we show some example results for a case study validating our approach. Our basic strategy is to find news articles pertaining to the policy statements, then perform internet searches for references to the news articles’ headlines and URLs. We have created a software tool that schedules repeating Google searches for the news articles and collects the results in a database, enabling the user to aggregate and analyse them to produce ranked tables of sites that reference the news articles. Using data mining techniques we can group data so that result reflects an overall aggregate score, taking into account multiple datasets, averaging out individual differences, or we can examine the differences between datasets, for example how the sites where the article is discussed changes over time.

Keywords: e-participation, social networking sites, news articles, news stories, political engagement, citizens’ opinions, dialogue

Acknowledgement: The WeGov project (no. 248512) is funded with support from the European Commission under the SEVENTH FRAMEWORK PROGRAMME THEME ICT 2009.7.3 ICT for Governance and Policy Modelling.

1. Introduction

The work reported here has been done within the context of the WeGov IST FP7 project. The project’s primary remit is to enable effective dialogue and engagement between e-governments and citizens, and a key feature of the project is that it uses social networking sites (SNS) as the primary communication channel. Before the project, there were a number of efforts to engage citizens with governmental policy, mainly using bespoke websites whose main drawback was that they were rarely used (see [1] for an example). WeGov is aiming to address this drawback by using tools the citizens already use: social networking sites, blogs, forums, etc.

The project supports its target audience of governmental policy makers with tools to enrich the two-way dialogue with citizens on SNS. The project’s philosophy has been to develop a set of tools for use by the user, along with a dashboard-based environment where the tools can be used individually and together. Tools are broadly gathered into three categories:

1. search (find citizens’ comments and opinions from social media);
2. analysis (summarise, interpret and understand the search results); and
3. injection (make postings into social media).
We have adopted a methodical approach for the development process of the software with frequent and iterative end user engagement so as to get requirements and feedback on development progress. The key aspects of our end user engagement process are similar to the good stakeholder engagement model [2] - these include the principles of transparency, meaningful dialogue, expectation-management, feedback and analysis. As part of user engagement, a number of use cases were designed showing how the WeGov analysis tools could provide a two-way dialogue with citizens [3], and the work reported here develops one of these use cases.

An important aspect of the work in WeGov is to protect the rights and privacy of citizens and policy makers. To address this, a legal and ethical analysis was conducted to provide us with an understanding of data protection issues and give an insight into transparency. This work has influenced the design and use of all parts of the toolbox, and has been reported elsewhere [4].

We already have tools in the WeGov toolbox to enable us to collect publicly-accessible comments and related data from social networks and other web sites, but we need to determine upon which sites the discussion is taking place. The work described here addresses this, motivated by a use case from external end users, namely to be able to find out where a news article is being discussed. This requirement is discussed in detail in the next section, which also sets out the research questions we aimed to answer. Following this, we describe our strategy to answer the research questions. We then describe the results for an example case study showing and how it may be used to benefit by its target audience.

2. Background & Problem Statement

During initial meetings with external end users, a particular need policy makers have was requested. This is the gathering citizens’ opinions as feedback to a particular statement by a politician. The first WeGov prototype covered this scenario as a first basic use case [5]. Here, the policy maker posts a statement into a social network, collects the citizens’ feedback (where it is publicly available) and runs the analysis components on the feedback. The result is a summary of the key themes and opinions over the sum total of the citizens’ comments [6].

The initial toolbox was presented to 29 office employees working for a parliamentarian of the German Bundestag with the aim of gathering feedback for the further development process [7]. During discussions with them, the consensus was that parliamentarians’ posts are unlikely to solicit a large amount of feedback, unless the politician is high-profile. They mentioned that “ordinary” parliamentarians’ posts typically generate below 100 comments. They confirmed that the requirement to test citizens’ reactions to politicians’ statements is important, but they need more comments to provide a statistically significant sample of opinions. A modification of the original use case was proposed by the Bundestag employees, where politicians’ statements are covered on the internet through news articles, which are in turn disseminated and discussed by citizens. Figure 1 outlines “The Newspaper Story” which capitalises on the effect of “indirect injections” [8] – this means the politician’s statement is disseminated by citizens rather than the politician. For example, a news article is written around the statement, and this is discussed over many different locations by citizens.

In the example in Figure 1, www.bbc.co.uk published a news article with the headline “State multiculturalism has failed, says David Cameron” [9]. Internet news sites provide the opportunity for readers to share and discuss news articles over diverse internet locations, and thus the story
may be propagated and discussed in many places on the internet by citizens. This news article was shared 31,309 times on Facebook and 1,922 times on Twitter.

![Figure 1: The Newspaper Story](image)

There is thus a vast amount of discussion on this news article, but the challenge is determining where it is being discussed. Addressing this challenge (step 5 in Figure 1) is the core of the work described in this paper: to identify the websites where a news article is disseminated, to give the WeGov analysis tools the opportunity to get more user comments as input, which should improve their accuracy.

Once we had a good idea of the core problem to be addressed, and began to consider its implications, a number of related challenges presented themselves. These are discussed next.

Once people start sharing the news article, discussion spreads out over different sites. This adds a new dimension to the requirements – it would be most helpful to the policy maker to track where the discussion on an article occurs over time from initial publication of the article.

News events are not usually covered with a single news article on one website – it is more likely that there are multiple articles written from different perspectives in different newspapers and on different websites, and each generates their own set of comments from the citizens that read them. In addition, news events develop and multiple articles are written, adding new developments and analysis. This adds a further requirement: to be able to track reactions to multiple articles, and to group them into sets, so they can be presented to analysis in logical groups.

It is also probable that the policy maker does not know the exact news articles they wish to track, or they only know of a subset of articles, so a related requirement is to enable searching for news articles to “bootstrap” the tracking of reactions to them.

Finally, policy makers are often specialists in, or are responsible for, a certain discipline or topic area, and it would be most helpful to them to determine key sites that are worth monitoring for general discussion and ideas around this topic.

### 2.1. Research Questions

Given the problem statement and the requirements above, a number of research questions arose:

1. How can we find out where a news article is being discussed?
2. How do the discussions’ locations change over time?
3. How can we track a news story containing many news articles?
4. How can we find news articles related to a press release or an MP’s statement?
5. Which are the important places a policy maker needs to monitor for discussion of items relevant to them?

3. Strategy

This section begins by outlining briefly how we addressed the research questions. After this, details pertaining to specific challenges for each question and their solutions are discussed.

- To address research question 1 (how to find where a news article was being discussed on the internet), we proposed a strategy whereby we perform internet searches for references to the news article and store the results in a database. The assumption underlying this strategy is that if the news story is referenced in a web page (i.e. it is returned as a hit in an internet search for the news article), then that web site has at least some relation to the news story.

- To track how the discussions’ locations changed over time (research question 2), we proposed to repeatedly (automatically) execute the same search on a regular basis, and store these results along with the original results in the database.

- Tracking a news story containing multiple articles (research question 3) is a matter of grouping searches and results together into a set for the story. This is simply a question of management of the searches and results; and maintaining links between sets of results, searches, news articles and news stories. We proposed to utilise relational database patterns to maintain these links - databases are well suited for this task.

- If we do not know the URL of the news articles we want to track, we will need to find the articles themselves (research question 4). For this we have proposed that we search selected newspapers’ websites for keywords from the press release or MP’s statement. The result set should be links to articles about the press release etc. Once we have this set of articles, they can be used as input to the strategies above.

- Finally, in order to determine useful sites for general monitoring (research question 5), we have proposed that we analyse groups of search results, to determine which web domains are most frequently featured, and how they are ranked.

- We also determined that we should be able to select arbitrary sets of search results for this analysis, so that we can determine the best sites given any set of results, from one single set, to all sets. This enables maximum flexibility to “data mine” the search results. We should be able to determine their own groups - for example multiple stories may be related because they are about a similar subject area. Grouping the results from these and analysing them produces a set of web domains pertinent for that subject area.

3.1. Searches

There are two main types of search:
Searches for comments and references to news articles. This is the major form of search (addressing research question 1, to find where news articles are being discussed), and returns result sets containing ordered hits for references to the news article.

Searches for news articles given the text or keywords of an MP’s statement. This is used when the news articles are not known, and the results can feed into the search for comments and references to news articles. This search addresses research question 4.

3.1.1. Searches for Comments and References to News Articles

The basic strategy we chose for this search was to automate data collection based on Google searches for places where the news article occurs, and to store the search results (hits) in a database. The same searches can be repeated periodically over time, and differences in where the news item is discussed can be highlighted.

The first thing we did was determine how to search the internet, and the solution was straightforward: we chose to use Google because it is the most popular search engine in the West. It has by far the largest market share of the search engines (see for example [10]), and appears to be the de facto choice for most users of the internet. As such, it is very likely to be used by many people who may want to comment on a news article – if someone wants to comment on a news article, they are likely to either:

- Comment directly on the news site itself;
- Comment on a website / SNS / forum / blog they already know about;
- Google search for the news article to find places where it is being discussed.

Through our use of Google, we will find pages with comments from people who do any of these actions.

We chose to perform two Google searches for each news article: firstly the article’s headline and secondly the news article’s web page URL. This enabled us to capture references to the news article (when the URL is quoted in a referring text), and the more general search for the headline, which uses natural language processing such as stemming, removal of stop words and fuzzy matching.

Google searching returns references to web pages (hits), ranked by Google’s proprietary algorithm. The Google ranking gives us a measure of how useful a hit will be. Google’s ranking of a search hit is important to us, as it determines the how the results will be presented to anyone searching, and we wish to find the most likely sites where people will go to make comments. Therefore our goal is in line with Google’s, to find the “best” sites for the search. We do not know the exact details of Google’s search algorithm as it is proprietary, but we do know it is founded upon citations – links to a web page behave as “votes” to increase its rank. What the algorithm contains is not important to us, but that it is used and relied upon by a vast user base, is. Google has a vested interest in returning useful hits to its users, and its market share indicates that it is doing just this.

To perform the actual searching, we used a Google Custom Search Engine (CSE) with automated control to repeatedly execute searches. The frequency of searching is configurable, and our initial configuration is that we search at the same time every other day. We created a relational database to hold the search results. For each hit in a search result set, we record the URL of a hit, its domain and the Google rank, as well as the search information such as the search query and the
date of searching. This enables us to perform analyses of how the ranking can change over time as well as aggregate analyses to determine the best sites given arbitrary sets of search results.

An example of search results for a news article, collected over a time period, is shown in Figure 2. The figure illustrates the relationship between the news article and repeated searches for its headline and URL, and also illustrates how we can address research question 2 (tracking the changes of discussion location for the news article over time).

Figure 2: Example News Article, Associated Searches & Results

The sets of hits in the search results above are analogous to the music charts denoting which records are the most popular at a given time. Our “hit parade” is of the top 100 web sites where the news article is discussed. The charts are updated periodically and web sites move up and down the chart according to their popularity. We also get new entrants to the chart and other web sites drop out of the top 100. Figure 2 illustrates this by showing the progress of some example websites—we can see the progress of domain A over time – it starts off at the top, and then drops down the list. Domain G is another example – it does not feature until the second search, but then rises to the top before tailing off. Figure 2 also illustrates that we may not get a full set of hits early on in the search, especially for a fresh news article. This is particularly true for the URL search, as it is highly specific and the search engine cannot use any natural language or fuzzy matching techniques to widen the result set. This is a desirable property for our purposes, as it means we are getting exact matches for the URL, and we can see its propagation.

3.1.2. Searching for News Articles

The second search type, where news articles themselves are found (research question 4), is only required when the news articles are not known, or the user wants to see newspaper reports of a particular policy statement. This search also uses Google, but requires that a limited section of the internet is searched – we only want news websites to be searched here. We created a second Custom Search Engine (named here the “Newspaper CSE”), that only searched a sample of UK news and newspaper sites (for example www.bbc.co.uk/news, www.telegraph.co.uk, etc).
The Newspaper CSE can be searched using keywords from a government press release or an MP’s statement, and because it is configured only to search newspaper and news sites, the results will be news articles. These news articles can then be used as inputs to the other search type (references and comments) to see where the articles are discussed on the wider internet.

The choice of news sites is customisable – the Newspaper CSE can be altered at any time, so additional news sites can be included. The Newspaper CSE could also be targeted to a specific purpose, for example a subject area, or geographical location (the Newspaper CSE searches could be local newspapers rather than national ones).

3.2. Data Analysis

By utilising different criteria to group the search results, we can answer research questions 3 (concerned with tracking the discussion locations for multiple news articles related to a news story) and 5 (a general aggregated analysis showing useful sites given multiple different data sets).

The grouping process may be thought of as a form of data mining known as an OLAP cube (see [11]). This allows data to be grouped and analysed along different dimensions. The dimensions we can utilise are: story names / keywords / subject areas, web domains, dates and article titles.

An example OLAP cube for a complete story is shown in Figure 3, alongside an analogous set of searches for news articles. Here we are comparing news articles against dates, and showing the ranked set of domains for each article and date.

![Figure 3: Example OLAP cube](image)

We can use slices from the OLAP cube as well – this means we only interested in one value in a particular dimension. For example, if we are only considering one story keyword, we only have a single value on that dimension.

In OLAP-style analysis we often want to aggregate values in a particular axis so we can examine the effect of other axes on the overall result. For example we may wish to investigate the aggregated ranking of all news articles in our story and how it changes over time. In the right hand side of Figure 3, this is collapsing the five layers into one and finding aggregated rankings in all the hit parades – taking into account all layers. This provides us with an overview of the top sites where the discussions on all our news articles are taking place over time, regardless of the articles.
We thus needed a means of aggregating the rankings, and we attempted different methods of determining the aggregated ranking. We originally attempted simple averaging, e.g. we took all the ranks for a particular web domain and computed their average. The major problem with this method was that it was highly sensitive to the number of records for that domain. If, for example, domain A had a single record at position 1, this would have an average value of 1, because there is only a single record. If domain B had ten records, and nine were at position 1 and the remaining record was at position 2, the average value would be 1.1. Given that the lower the average the better in this example, this means that the consistent high performer, domain B, with 9 top positions, was apparently outperformed by domain A, who only appeared once.

Next, we looked at different weighting algorithms, so as to give more importance to the higher positions, but these suffered similar problems to the straightforward average. It was therefore decided that we needed to take account of the number of occurrences a domain has, as well as its position in each occurrence. What we wanted to find was consistent good performers (e.g. domain B above), rather than ones with few high positions but no other records (who could be considered “lucky” without further evidence).

The Bayesian Average method (see for example [12] or [13]) is purpose-built for this task. It reduces the effect of anomalous values by considering the average number of occurrences for each domain as well as the average value per occurrence. It does this by calculating a corrected ranking that takes the number of occurrences a domain has into account using the two following principles:

- the more occurrences a domain has, the closer its corrected ranking value is to its uncorrected value; and
- the fewer occurrences a domain has, the closer its corrected ranking is to the average ranking value of all domains.

Thus, the more times a domain appears in search results, the more “believable” its scores are.

After the data slicing, aggregation and Bayesian averaging, we have ranked tables of “chart positions” for each domain that take into account the way we have sliced the data, the chart positions and the number of votes for each chart position. Using this aggregation and the OLAP cube technique, we can show the aggregated ranking of multiple search results, for example:

- A single story (e.g. all the searches over time to date for the story)
- The time development of a single story (e.g. where discussions for all news articles in the story change over time)
- Multiple stories (e.g. the user can select related stories to find out where people are talking about them)
- One day (e.g. all searches on one single day independent of story)
- Everything (e.g. all results for all stories to date).

To illustrate the collapsing of Figure 3’s news articles mentioned above, Figure 4 shows an example output table for a single news story’s development over time. This is an overall aggregated ranking of the domains for all news articles (both for the news articles’ headlines and URLs) and searches over time to date, for that news story.
4. Results & Initial Evaluation

We implemented a software tool to perform the searches and analyses described above. We show here an example of its output for a case study of a news article. The main UI of the software tool with the article and its searches displayed is shown in Figure 5.

Figure 5: News Story Tracking

The example is based on a single news story, from the BBC news website. This concerned a story about plans for a national public-sector strike, published on 14 September 2011. Figure 6 shows a results page, showing the Bayesian Average ranking, position, and number of occurrences for different domains over all times the news article is searched for (14 September 2011 to 30 November 2011). Because they reference the news article, the sites can be useful places for the policy maker to watch for opinions on their policy statements. In the results table, the domain is only shown, and we use this as a gateway to the actual results – we click on a domain and we can see the hits associated with that domain. A hit contains the URL of the page, Google’s “snippet” and the rank. Often, a domain in a result table will contain the aggregated results of multiple searches, and therefore the same web page may be returned multiple times. In this case, the page is

1 Available at: http://www.bbc.co.uk/news/business-14907909 & retrieved on 2011-12-01.
returned with an indicator of how many times it appears in the search results, and how its position changed over time.

![Figure 6: Bayesian Average Overall Rankings](image)

The table is sorted by the Bayesian Average of the Google rankings. The smallest is first – this means the most interesting sites as determined by Google are at the top. The number of occurrences of each site is also shown, giving an indication of how many data points were used to compute the overall Bayesian Average ranking, and we can see that there are reasonable numbers of samples (i.e. search results) for each site. We can also see that www.bbc.co.uk is the highest position – this is reasonable and to be expected, since the BBC needs to index its own pages, but is rather obvious. This is no problem– it is a known good site, so we just look further down the list.

The “category” column allows the user to mark some sites as known good sites, or sites that are not useful. Uninteresting sites may be ones based on advertising or contain content is irrelevant to the policy maker. The policy maker can filter out a domain that is not interesting to them by marking it as “uninteresting” in the “category” column, and it is ignored in this and all other result tables. The data from uninteresting sites is still collected and analysed, and the blacklist of uninteresting sites can be edited at any time to return the blacklisted sites to the analysis results.

The overall rankings may be broken down by time, and Figure 7 shows rankings per week. The results are grouped per week and are for the single news article. Here we see a more varied set of sites, and their positions change week by week.

![Figure 7: Search Results - Bayesian Average Rankings per Week](image)

The arrows in the figure illustrate the movement of some particular domains, and we discuss one of them in more detail next. The Digital Spy forums started off in position 3, peaked in the second week at position 2, and then dropped to position 5 before dropping out of the visible data. This was because it contained two threads that discussed the BBC news article. The first [14] was a
thread discussing the article, and the first post included a link to the BBC news story. This thread had 120 posts – the first was made on 14 September 2011, and the last was made on 7 October 2011. The bulk of the activity was in the first week. The second thread [15] was a poll about whether people supported the strike, together with opinions given in the thread. In the poll, 120 people voted Yes (44.28%), 143 voted No (52.77%), and 8 voted “Don’t know/care” (2.95%). The thread accompanying the poll contained 522 posts, the first was made on 14 September 2011, and the last was made on 19 September 2011. The bulk of the posts were made over 15-18 September.

The pattern is common – an event occurs, and there is a flurry of activity concerning it, which peaks and then tails off. Given that there may be a lag in Google’s indexing of the Digital Spy forums, the activity on the forum and the rankings in the table give a reasonable match. The important point is there is genuine and useful debate in this forum. Other forums with debate on this topic were also highlighted by the results table. Some debates are more interesting than others, but overall the method of finding where the debate is occurring shows promising initial results.

5. Conclusions

This paper has described a method whereby a governmental policy maker can discover where policy statements are discussed, and we have shown some example results validating our approach. Our strategy was to assume that news articles are written about the policy statements, and these are discussed over the internet. To enable us to find where a news article is being discussed, we determined that we need to search for references to its headline and URL. We scheduled and repeated Google searches for news articles, and collected the results in a database, enabling us to aggregate and analyse them to produce ranked tables of sites that reference each news article. Using data mining techniques such as the OLAP cube, we can group data so that the result reflects an overall aggregate score, taking into account multiple datasets, averaging out individual differences. Alternatively, we can examine the differences between datasets, for example how the sites where the article is discussed changes over time. We have concluded that Google is a good search engine to determine references to a news article, but our technique is not limited to just one search engine – if another appears that suits our purposes better, we can easily adopt it without adjustment of our technique.

There are two major elements of further work. Firstly, having conducted our initial evaluation to determine that useful results are returned, we need to present the work to policy makers, so that they can make comments on the search results, and how the results are presented. Secondly, now we can find out where people are talking about news articles, we need to integrate the software tool with the rest of the WeGov toolkit, so that the results of this work can be fed into more detailed searches to find out what people are saying.
